

1 FROM DESIGN TO DEPLOYMENT: A DIGITAL 2 ARCHITECTURE STRATEGY

3 ABSTRACT

4 The life sciences industry invests heavily in digital technologies, yet pharmaceutical and
5 biopharmaceutical manufacturers continue to struggle with fragmented data landscapes, manual
6 reconciliation, and limited return on digital initiatives. This paper argues that the root cause is
7 architectural, not technological: digital systems designed to optimize individual lifecycle phases fail
8 to preserve the relationships between manufacturing intent, execution reality, and quality evidence
9 as products move from early clinical development through commercial production, technology
10 transfer, contract manufacturing, and product lifecycle management.

11 This paper introduces the Intent-Driven Digital Core (IDDC), a four-layer architectural framework
12 — Semantic, Event, Context, and Evidence — that preserves manufacturing intent as a persistent,
13 machine-readable construct across the full product lifecycle, from the earliest process development
14 activities through commercial-scale operations and beyond. The IDDC builds on established
15 standards (ISA-88, ISA-95, ICH quality guidelines) and extends them by explicitly addressing
16 semantic persistence, contextual binding at the point of execution, and progressive evidence
17 accumulation. The framework is evaluated through alignment with industry consortium work
18 (Pistoia Alliance CMC Process Ontology, BioPhorum Data Enablement Program), a practitioner case
19 study in alarm management for cell therapy manufacturing, and regulatory requirements including
20 21 CFR Part 11, EU GMP Annex 11, and current data integrity guidance.

21 The paper demonstrates how intent-driven architecture accelerates the journey from discovery to
22 patient — technology transfer becomes repeatable rather than bespoke, batch disposition shifts
23 from retrospective reconstruction to continuous evaluation, and AI deployment gains the
24 contextual grounding required for trust in regulated environments. The implications extend beyond
25 technical architecture to organizational governance — treating manufacturing intent as a lifecycle
26 asset requiring explicit stewardship reshapes roles, responsibilities, and operating models.

27 Limitations, including the framework's design science methodology and scope boundaries, are
28 discussed alongside directions for future empirical validation and cross-industry applicability.

29 EXECUTIVE SUMMARY

30 The life sciences industry is undergoing a fundamental shift in how therapies are designed,
31 developed, transferred, and manufactured. Scientific innovation is accelerating, manufacturing
32 modalities are diversifying, and regulatory expectations increasingly emphasize data integrity,
33 traceability, and lifecycle control (FDA, 2011; ICH, 2009). In response, organizations are investing
34 heavily in digital technologies across discovery, development, and manufacturing. Yet despite this
35 investment, many struggle to achieve continuity, scalability, and sustained value from their digital
36 initiatives. While the integration of artificial intelligence (AI) is transforming drug discovery—
37 dramatically increasing both speed and precision (Jiménez-Luna et al., 2021)—development and
38 manufacturing processes have not progressed at a comparable rate, creating structural bottlenecks
39 that delay the delivery of timely and affordable treatments (McKinsey & Company, 2016; ISPE,
40 2023).

41 Industry research documents that 70% or more of digital transformation initiatives fail to achieve
42 their stated objectives, with regulated manufacturing environments experiencing particularly high
43 failure rates attributed to underestimation of data context, governance, and semantic consistency

44 requirements when scaling beyond isolated use cases (McKinsey & Company, 2016; World
45 Economic Forum, 2022; BioPhorum, 2023). This paper argues that architectural discontinuities,
46 rather than individual technologies, are the primary barrier to sustainable digital value. To
47 overcome these barriers, organizations must design and govern a digital architecture and operating
48 model that ensures manufacturing intent, context, and evidence persist from discovery through
49 development, initial design, deployment, routine manufacture, and transfer to new sites. When
50 digital systems are implemented in isolation, critical meaning is lost at lifecycle handoffs (see
51 Figure 1 and Figure 3) requiring repeated interpretation, manual reconciliation, and risk-based
52 judgment under uncertainty.

53 A robust digital architecture must therefore do more than integrate systems or move data. It must
54 enable consistent interpretation of scientific and manufacturing intent as that intent evolves from
55 early development through commercial production, preserving the relationships between process
56 design, execution reality, and quality expectations. This continuity is essential to supporting reliable
57 scale-up, effective technology transfer (see Figure 6) as defined in WHO Technical Report Series
58 guidelines (WHO, 2011; 2022), and confident batch disposition (see Figure 5) in increasingly
59 complex manufacturing networks.

60 The strategy described in this paper is grounded in an intent-driven operational model, in which
61 manufacturing intent is explicitly defined, governed, and instantiated across lifecycle phases. This
62 model, consistent with ICH Q8 quality-by-design principles (ICH, 2009) and ICH Q10
63 pharmaceutical quality system requirements (ICH, 2008), facilitates tighter alignment between
64 discovery and development activities—where process understanding is generated—and
65 manufacturing execution—where that understanding must be applied consistently under regulated
66 conditions. By treating data, context, and evidence as lifecycle assets rather than phase-specific
67 artifacts, the approach reduces friction at transitions and enables earlier, more informed decision-
68 making in accordance with ICH Q12 lifecycle management principles (ICH, 2019).

69 At the heart of this strategy is the **Intent-Driven Digital Core (IDDC)**: a conceptual framework
70 introduced in this paper to describe a persistent architectural foundation that preserves semantic
71 meaning, execution context, and quality-relevant evidence across the end-to-end lifecycle. Unlike
72 conventional data warehouses, point-solution integrations, or technology stacks, the Intent-Driven
73 Digital Core does not replace existing systems or prescribe specific technologies. Instead, it
74 provides a unifying architectural construct that allows diverse systems to operate against a shared
75 understanding of meaning, time, and state—ensuring data is not only transmitted, but interpretable
76 and actionable throughout the lifecycle in compliance with ALCOA+ (Attributable, Legible,
77 Contemporaneous, Original, Accurate, plus Complete, Consistent, Enduring, and Available)
78 principles (FDA, 2018; MHRA, 2018). These same characteristics become prerequisites for
79 trustworthy AI: as organizations adopt machine learning and large language models, the
80 attributability, provenance, and contextual completeness that ALCOA+ demands grow more
81 essential, not less, because models inherit the integrity of the data and context they consume. This
82 foundation enables downstream capabilities to be deployed with greater trust, scalability, and
83 regulatory confidence.

84 The Intent-Driven Digital Core is composed of interdependent capabilities, including explicit
85 semantic definitions grounded in industry ontologies (Pistoia Alliance, 2023; 2024; NIIMBL, 2021),
86 event-driven representations of execution reality aligned with ISA-88 batch control concepts (IEC,
87 2013), contextual binding of process, equipment, material, and quality information consistent with
88 ISA-95 integration models (IEC, 2013), and structured evidence suitable for quality review and
89 regulatory compliance. Together, these capabilities enable organizations to move from ad-hoc
90 digital initiatives toward an integrated, governed environment that supports traceability,
91 compliance, and innovation. Industry research on digital convergence in manufacturing and life

92 sciences similarly highlights the importance of architectural foundations and governance in scaling
93 digital value beyond isolated projects (World Economic Forum, 2022; ISPE, 2023; BioPhorum,
94 2023).

95 Importantly, architecture is not merely a technical exercise; it is fundamentally socio-technical.
96 Preserving and operationalizing manufacturing intent across the lifecycle requires redefining roles
97 and responsibilities, including ownership of intent, stewardship of shared data assets, integration of
98 quality evidence, and leadership across digital tech transfer activities—organizational capabilities
99 emphasized in the ISPE Pharma 4.0 Operating Model (ISPE, 2019). Without enabling people to
100 operate within the architectural construct, even well-designed technical solutions fail to deliver
101 sustained value.

102 This paper develops these concepts across the manufacturing lifecycle, demonstrating how an
103 intent-driven digital architecture improves continuity, reduces manual reconciliation, enhances
104 trust in analytics and AI in accordance with emerging AI governance frameworks (NIST, 2023;
105 ISO/IEC, 2023), and supports scalable technology transfer. Drawing on industry research and
106 practical manufacturing realities documented through consortium participation (Pistoia Alliance
107 CMC Process Ontology project; BioPhorum Data Enablement Program), it presents a strategy that
108 places architectural continuity at the center of digital execution in regulated life sciences
109 environments.

Key Takeaways

Digital architecture determines value realization. Sustainable digital transformation in life sciences manufacturing depends on architectures that preserve intent and context across the full product lifecycle.

Intent-Driven Digital Core as the strategic foundation. An intent-centric core that harmonizes semantics, execution events, context, and evidence enables trustworthy operations, analytics, AI, and scale.

People and roles are part of the architecture. Organizational capabilities—not just tools—must evolve to steward intent and evidence across functional boundaries.

Outcomes over components. Architectural continuity enables scalable manufacturing, quality, and technology transfer rather than incremental, phase-specific improvements.

213 1. INTRODUCTION: THE ARCHITECTURE GAP IN DIGITAL 214 MANUFACTURING

215 The life sciences industry is experiencing sustained pressure to accelerate the translation of
216 scientific innovation into reliable, scalable, and compliant manufacturing operations. Advances in
217 discovery science, including high-throughput experimentation, computational biology, and AI-
218 enabled drug design, are generating new therapeutic candidates at unprecedented speed. At the
219 same time, manufacturing organizations are required to support increasingly diverse modalities,
220 compressed development timelines, and expanding global production networks—all while
221 maintaining stringent regulatory compliance and product quality standards.

222 In response, companies have invested heavily in digital technologies across the lifecycle, including
223 electronic laboratory systems (LIMS/LES), manufacturing execution systems (MES), advanced
224 analytics platforms, digital twins, and artificial intelligence. These investments are often justified by
225 their potential to improve efficiency, enhance insight, and enable faster decision-making
226 (Westerman et al., 2014; Vial, 2019). However, despite widespread adoption, many organizations
227 struggle to translate digital capability into sustained, end-to-end value across discovery,
228 development, and manufacturing. Research on digital transformation consistently demonstrates
229 that technology deployment alone does not guarantee business value—successful transformation
230 requires simultaneous development of both digital capability and organizational leadership
231 capability (Westerman et al., 2014).

232 Industry analyses show that digital initiatives frequently stall beyond pilot phases, fail to scale
233 across sites, or require significant manual intervention to remain operationally viable. This pattern
234 is particularly evident at lifecycle transition points—such as process scale-up, site deployment, and
235 technology transfer—where meaning, context, and accountability must be preserved across
236 organizational and system boundaries. The result is a landscape characterized by fragmented data,
237 duplicated effort, and increasing reliance on expert interpretation to reconcile inconsistencies
238 between systems and stages.

239 This paper argues that these challenges are not primarily technological in nature. Rather, they
240 reflect a fundamental architecture gap between how manufacturing knowledge is generated,
241 represented, and governed during discovery and development, and how it is executed, reviewed,
242 and transferred during routine manufacturing operations. Enterprise architecture theory has long
243 recognized that information systems architecture must provide logical constructs for defining and
244 controlling the integration of system components (Zachman, 1987), and that architecture serves as
245 strategy by enabling consistent execution across organizational boundaries (Ross et al., 2006).
246 When digital systems are implemented to optimize individual lifecycle phases or functional
247 domains in isolation, they fail to preserve the relationships between scientific intent, execution
248 reality, and quality evidence—a pattern that integration architecture literature identifies as
249 semantic discontinuity (Hohpe & Woolf, 2003). Over time, this fragmentation manifests as rework,
250 delay, and increased operational risk.

251 The consequences of this gap are most visible in areas that demand lifecycle continuity. Technology
252 transfer requires process understanding, control strategies, and quality expectations to be
253 reinterpreted and re-encoded for each new site or partner. Batch disposition depends on
254 reconstructing execution context and evidence after the fact, often across multiple systems.
255 Advanced analytics and AI struggle to gain trust when data lacks consistent semantics, provenance,
256 or temporal alignment. In each case, the organization compensates for architectural shortcomings
257 through manual review, local workarounds, and tacit knowledge held by a limited number of
258 experts.

259 Recent industry research highlights this structural challenge. Studies on digital transformation in
260 regulated manufacturing environments note that organizations frequently underestimate the
261 importance of data context, governance, and semantic consistency when scaling digital solutions
262 beyond isolated use cases (McKinsey & Company, 2016; Deloitte, 2021). Similarly, pharmaceutical-
263 specific maturity frameworks such as the ISPE Pharma 4.0 Digital Maturity Model (ISPE, 2023) and
264 the BioPhorum Digital Plant Maturity Model (BioPhorum, 2023) emphasize that digital value is
265 constrained not by analytics capability, but by the ability to integrate process knowledge, execution
266 data, and quality evidence into a coherent, lifecycle-aware foundation. These industry consensus
267 models identify architectural integration and semantic interoperability as foundational maturity
268 dimensions that must precede advanced analytics deployment.

269 Addressing this architecture gap requires a shift in perspective. Rather than viewing digital
270 transformation as a sequence of technology deployments, organizations must design for lifecycle
271 continuity from the outset—what digital transformation research characterizes as moving from
272 disruption response to strategic value creation (Vial, 2019). This involves explicitly defining
273 manufacturing intent, ensuring that intent can be instantiated consistently across systems, and
274 preserving the contextual and evidentiary relationships necessary for quality, compliance, and
275 learning. Architecture, in this sense, becomes the mechanism by which discovery, development, and
276 manufacturing are unified—through shared semantic foundations rather than uniform tooling.
277 Industry reference frameworks including TOGAF (The Open Group, 2018) and domain-specific
278 maturity models (ISPE, 2023; BioPhorum, 2023) similarly emphasize that sustainable digital value
279 requires architectural foundations that enable semantic consistency across organizational
280 boundaries.

281 The remainder of this paper develops an architectural strategy to address this gap. It introduces
282 manufacturing intent as the foundational construct, defines the Intent-Driven Digital Core (IDDC) as
283 the mechanism for preserving intent and context across the lifecycle, and explores the implications
284 for people, governance, technology transfer, batch disposition, and advanced analytics. Together,
285 these elements form a cohesive approach to moving from fragmented digital initiatives toward
286 sustainable digital continuity in life sciences manufacturing.

287 1.1. KEY TERMS INTRODUCED IN THIS PAPER

288 The following terms are introduced or used with specific architectural intent in this paper.
289 Definitions are provided upfront to ensure consistent interpretation across lifecycle phases,
290 functions, and disciplines.

291 1.1.1. CORE ARCHITECTURAL CONCEPTS

Term	Definition
Digital Continuity	The operational outcome achieved when manufacturing intent, execution context, and quality evidence are preserved across discovery, development, manufacturing, technology transfer, and product lifecycle management including post-approval changes and product retirement without re-interpretation or manual reconstruction. Digital continuity is the goal; the IDDC is the architectural mechanism for achieving it.
Intent-Driven Architecture	An architectural approach in which manufacturing intent is explicitly defined, governed, and bound to execution and evidence across the lifecycle, rather than being implicitly embedded in systems, documents, or local practices.
Intent-Driven Digital Core	A persistent architectural construct that preserves semantic meaning, execution events, contextual relationships, and quality evidence across the

Term	Definition
(IDDC)	manufacturing lifecycle, enabling downstream capabilities without loss of intent or meaning. The IDDC is the primary artifact introduced by this research.
Architectural Continuity	The condition in which manufacturing meaning, intent, and evidence remain interpretable and traceable despite changes in systems, sites, products, or lifecycle phase.
Architectural Discontinuity	The structural condition in which manufacturing meaning, context, or evidence is lost, reinterpreted, or reconstructed at lifecycle transitions due to inadequate architectural provisions for semantic and contextual persistence. Architectural discontinuity is the central problem this paper addresses; the IDDC is designed to prevent it.
Semantic Interoperability	The capability to exchange data between systems such that the meaning of that data is preserved and consistently interpreted by all parties, beyond mere syntactic or format compatibility. Semantic interoperability requires shared ontologies or formal vocabularies and is a prerequisite for lifecycle continuity.
Architectural Construct	A conceptual structure that defines responsibilities, relationships, and integration patterns independent of specific platforms, tools, or implementations. The IDDC is an architectural construct; specific technology choices (e.g., event streaming platforms, ontology tooling) are implementation decisions.

292 1.1.2. CORE CAPABILITIES OF THE IDDC

Term	Definition
Semantic Layer	The architectural capability responsible for encoding shared definitions, relationships, and meaning for processes, materials, equipment roles, and quality attributes.
Event Layer	The capability that captures manufacturing execution as time-coherent events and state transitions, enabling accurate reconstruction of what occurred, when it occurred, and under what conditions.
Context Layer	The capability that binds execution events to relevant process, material, equipment, site, and quality context at the point of generation, eliminating downstream inference.
Evidence Layer	The capability that accumulates execution data as review-ready evidence, preserving lineage, provenance, integrity, and suitability for quality and regulatory decision-making.

293 1.1.3. REGULATORY AND QUALITY CONCEPTS

Term	Definition
Control Strategy	A planned set of controls, derived from current product and process understanding, that ensures process performance and product quality (ICH Q10, 2008). Control strategies span the product lifecycle and must evolve with enhanced process understanding.

Process Understanding	A comprehensive body of knowledge regarding a process and its relationship to product quality, including identification of critical process parameters, their acceptable ranges, and the scientific rationale for those ranges (ICH Q8(R2), 2009). Process understanding is generated during development and must be preserved and accessible throughout the commercial lifecycle.
Quality by Design (QbD)	A systematic approach to pharmaceutical development that begins with predefined objectives and emphasizes product and process understanding and process control, based on sound science and quality risk management (ICH Q8(R2), 2009). QbD principles inform how manufacturing intent should be defined and governed.
Design Space	The multidimensional combination and interaction of input variables and process parameters that have been demonstrated to provide assurance of quality (ICH Q8(R2), 2009). Design space represents formalized process understanding that must be preserved across lifecycle transitions.

294 1.1.4.LIFECYCLE AND OPERATING MODEL CONCEPTS

Term	Definition
Manufacturing Intent	The explicit articulation of process objectives, constraints, control strategies, and quality expectations that define how a product is intended to be manufactured, independent of any specific execution system or site.
Lifecycle Asset	Any architectural element (such as intent definitions, semantic models, or evidence structures) that must persist and evolve across multiple lifecycle phases rather than being created and discarded within a single phase.
Capability Stewardship	Ongoing accountability for the health, evolution, and fitness-for-purpose of architectural capabilities, distinct from time-bounded project delivery.
Intent Ownership	Explicit accountability for defining, maintaining, and governing manufacturing intent across lifecycle phases to ensure consistent interpretation and controlled evolution.

295 1.1.5.OUTCOMES ENABLED BY THE ARCHITECTURE

Term	Definition
Continuous Batch Disposition	A quality operating model in which batch release readiness is evaluated progressively as evidence is generated, rather than reconstructed retrospectively at the end of execution.
Digital Technology Transfer	The ability to transfer manufacturing processes between sites or partners using portable intent, comparable execution context, and reusable evidence rather than site-specific re-interpretation.
Downstream Capabilities	Digital capabilities such as batch disposition, analytics, AI, and digital technology transfer that consume architectural foundations but do not define or own core meaning.

296 1.1.6.AI-RELEVANT ARCHITECTURAL CONCEPTS

Term	Definition
------	------------

AI Enablement (Architectural Sense)	The condition in which data, context, and evidence are sufficiently explicit, stable, and governed to support scalable, trustworthy AI deployment in regulated manufacturing environments.
Semantic Drift	The gradual loss or divergence of meaning that occurs when definitions or assumptions change without controlled governance, often reintroduced through manual workarounds.
Concept Drift	The degradation of AI model performance caused by changes in underlying processes, data distributions, or context that are not reflected in model governance or retraining.
Socio-Technical Architecture	An architectural perspective that treats people, roles, and decision rights as integral components of the system, alongside technology and data.

297 **2. MANUFACTURING INTENT AS THE ARCHITECTURAL ANCHOR**

298 A recurring challenge in life sciences manufacturing is not the absence of process knowledge, but
 299 the inability to preserve that knowledge coherently as it moves across lifecycle phases. The ICH
 300 quality guidelines establish process understanding—comprehensive knowledge of the process and
 301 its relationship to product quality—as foundational to pharmaceutical development (ICH, 2009).
 302 During discovery and development, this understanding is generated through experimentation,
 303 modeling, and iterative learning consistent with Quality by Design (QbD) principles (Yu, 2008;
 304 Rathore & Winkle, 2009). As products progress toward commercialization, process understanding
 305 must be translated into executable instructions, control strategies, and quality expectations that can
 306 be applied consistently across sites and over time (ICH, 2008). In practice, this translation is rarely
 307 seamless, creating what FDA guidance characterizes as gaps between process design, qualification,
 308 and continued verification stages (FDA, 2011).

309 This paper defines manufacturing intent as the structured expression of what must be done, why it
 310 must be done, under what constraints, and how success is determined in a manufacturing context.
 311 This concept synthesizes and extends established regulatory constructs: ICH Q8's design space (the
 312 multidimensional combination of input variables and process parameters demonstrated to provide
 313 quality assurance), ICH Q10's control strategy (planned controls derived from process
 314 understanding), and ICH Q8's critical quality attributes and critical process parameters (ICH, 2009;
 315 ICH, 2008). Manufacturing intent encompasses process objectives, critical parameters and ranges,
 316 material and equipment roles, quality attributes, and acceptance criteria. Importantly, it also
 317 includes the rationale behind these elements—the relationships and assumptions that explain why
 318 particular controls or decisions matter, what Garcia-Munoz et al. (2010) characterize as the
 319 "knowledge component" of design space that is often lost in translation to manufacturing.

320 Manufacturing intent is therefore broader than a recipe, batch record, or specification. It is the
 321 unifying construct that links scientific understanding to operational execution and quality
 322 oversight, fulfilling what ICH Q10 envisions as lifecycle knowledge management (ICH, 2008). When
 323 intent is not explicitly defined and governed, it becomes fragmented across documents, systems,
 324 and teams, increasing the likelihood of divergence as products scale and manufacturing networks
 325 expand.

326 **2.1. FRAGMENTATION OF INTENT ACROSS THE LIFECYCLE**

327 In many organizations, manufacturing intent is implicitly encoded multiple times as a product
 328 progresses from development to routine manufacture. Early-stage intent — from the earliest
 329 clinical manufacturing at laboratory and pilot scale through process development and scale-up —

330 may be captured in development reports, experimental data sets, and design rationales. As
331 processes are industrialized, portions of that intent are re-expressed in process descriptions, MES
332 configurations, automation logic, and quality documentation. Each translation introduces the risk of
333 semantic drift, simplification, or loss of context.

334 Organizations that defer intent capture to later lifecycle stages — treating it as documentation to be
335 assembled rather than architecture to be built — pay for that deferral at every subsequent
336 transition. The cost is not merely inefficiency; it is structural. Without an explicit intent record from
337 the earliest process development activities, each downstream team must reconstruct rationale
338 through conversations, cross-departmental inquiries, and institutional memory — resources that
339 degrade as personnel change and timelines compress. The architectural imperative is clear: the
340 intent record must begin when the first process design decision is made, and it must persist and
341 accumulate as the product matures. Equally important, that record must remain accessible to every
342 downstream team that depends on it; an intent record that exists but cannot be readily found or
343 queried imposes the same reconstruction cost as no record at all.

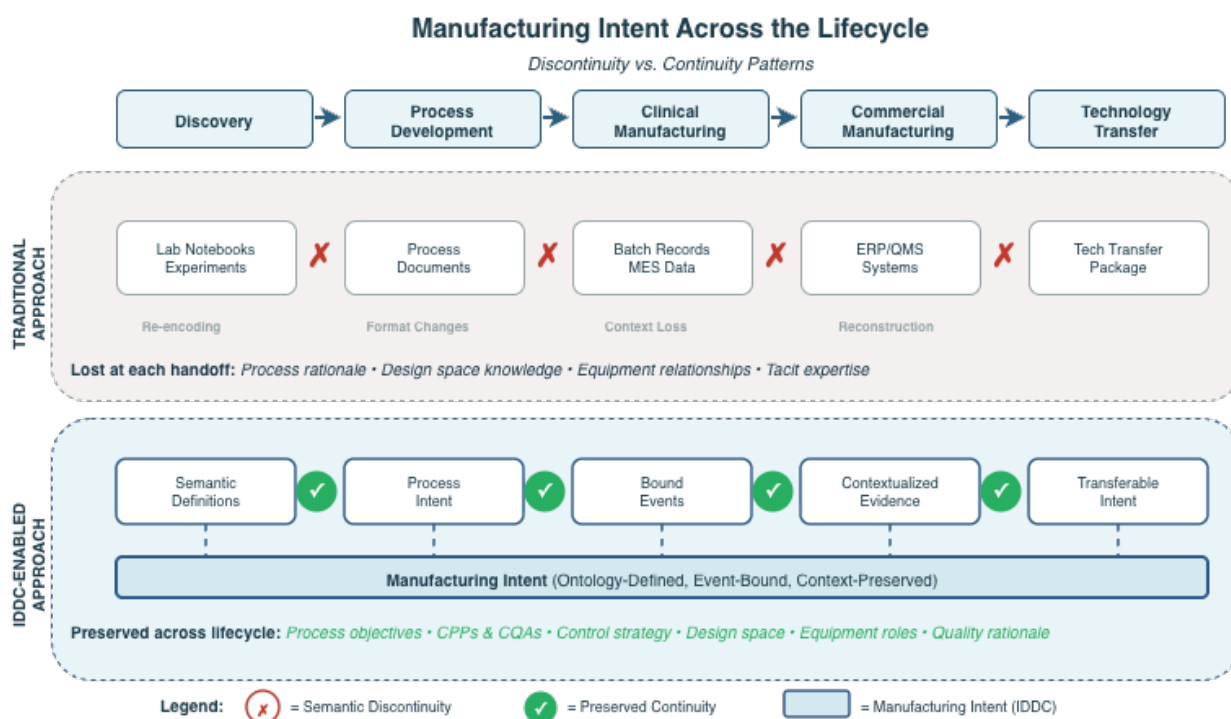

344 This fragmentation is particularly pronounced at lifecycle transition points, such as process scale-
345 up, site deployment, and technology transfer. At these stages, intent is often reconstructed from
346 artifacts rather than transferred as a coherent whole. The result is increased reliance on expert
347 interpretation, local workarounds, and retrospective justification to reconcile differences between
348 design assumptions and execution reality.

349 Industry research and regulatory observations have documented this challenge extensively. Studies
350 on pharmaceutical manufacturing digitalization note that organizations frequently struggle to
351 maintain alignment between process knowledge generated during development and the controls
352 applied during commercial production (McKinsey & Company, 2016; BioPhorum, 2023). This gap is
353 particularly pronounced in complex or rapidly evolving modalities such as biologics and cell
354 therapies, where process-product interdependencies demand tighter knowledge continuity (Nasr
355 et al., 2017). FDA has similarly observed that lifecycle stages often operate as disconnected
356 activities rather than integrated elements of a unified quality system (FDA, 2011). Without a
357 consistent architectural anchor, intent becomes contextualized to a specific phase or system rather
358 than preserved across the lifecycle—what Kourti (2006) describes as the "informatics gap"
359 between process development and manufacturing. Figure 1 illustrates this contrast between
360 traditional discontinuity patterns and the continuity enabled by an intent-driven approach.

361 2.2. INTENT AS A LIFECYCLE ASSET

362 Treating manufacturing intent as an architectural anchor requires a shift in how it is managed,
363 aligning with ICH Q12's vision of product lifecycle management through established conditions and
364 post-approval change management protocols (ICH, 2019). Rather than being viewed as a collection
365 of phase-specific artifacts, intent must be treated as a lifecycle asset—explicitly defined, versioned,
366 and governed as it evolves. This approach operationalizes ICH Q10's concept of a pharmaceutical
367 quality system that spans the product lifecycle and enables continual improvement through
368 knowledge management (ICH, 2008). Intent must adapt as scientific understanding improves and
369 operational constraints change; however, those changes should be deliberate, traceable, and
370 interpretable across all consuming systems and stakeholders—characteristics that ICH Q9(R1)
371 identifies as essential for knowledge-based quality risk management (ICH, 2023).

372 In practice, intent does not evolve as a simple linear progression. The product lifecycle moves
 373 forward — from early development through clinical manufacturing, scale-up, technology transfer,
 374 and commercial production — but at specific points, new evidence or operational experience
 375 triggers a structured loopback to an earlier design decision. A process parameter established
 376 during development may require revision when commercial-scale equipment introduces different
 377 mixing dynamics. A control strategy designed for a single clinical site may need adaptation when
 378 transferred to a contract manufacturer with different infrastructure. Each loopback is targeted and
 379 additive: the original intent remains as the anchor, the trigger for change is documented, the
 380 revised approach is justified by evidence that the intended outcome is preserved, and the updated
 381 rationale feeds forward into all subsequent lifecycle activities. This pattern — forward progression
 382 with structured, versioned loopbacks — ensures that the intent record compounds in depth and
 383 defensibility as the product matures, rather than degrading at each transition. For regulators and
 384 auditors, the result is a traceable narrative: not merely what was done, but why it was done, what
 385 changed, and why the change is justified.

386 Figure 1. Manufacturing Intent Across the Lifecycle: Discontinuity vs. Continuity Patterns.
 387 The IDDC preserves semantic meaning across lifecycle transitions through ontology-defined intent and context binding.

388 From an architectural perspective, this means that intent must be:

- 389 • Explicit, rather than embedded implicitly in system configurations or documents
- 390 • Structured, such that relationships between process elements, constraints, and quality expectations are machine- and human-interpretable
- 391 • Persistent, remaining accessible and meaningful across lifecycle phases and sites

393 By anchoring the architecture around intent, downstream systems are no longer responsible for
 394 inferring meaning from isolated data points. Instead, they instantiate and consume a shared
 395 representation of what the organization intends to achieve and control through manufacturing.

396

397 2.3. RELATIONSHIP BETWEEN INTENT, EXECUTION, AND EVIDENCE

398 Manufacturing intent sits at the intersection of design, execution, and quality. It defines what
399 execution should accomplish, but it must also be reconciled continuously with what occurs on the
400 shop floor. Execution events, in turn, generate evidence that demonstrates whether intent has been
401 met.

402 When intent is weakly defined or inconsistently applied, this relationship breaks down. Execution
403 data becomes difficult to interpret, and quality review shifts toward reconstructing context rather
404 than assessing conformance. Conversely, when intent is explicit and architecturally anchored,
405 execution events can be contextualized at the point of generation, and evidence can be accumulated
406 progressively rather than assembled retrospectively.

407 This relationship is central to modern quality paradigms, which emphasize lifecycle knowledge
408 management and continuous verification rather than episodic review. FDA's Process Analytical
409 Technology (PAT) framework established the principle that quality should be built into products
410 through design and continuous process understanding rather than tested into finished products
411 (FDA, 2004). ICH Q10 extends this vision by requiring pharmaceutical quality systems to integrate
412 process performance and product quality monitoring with corrective and preventive action and
413 knowledge management (ICH, 2008). More recently, regulatory discussions of real-time release
414 testing and continuous manufacturing have reinforced that quality oversight should be integrated
415 with—not separated from—process execution (Nasr et al., 2017). An intent-driven architecture
416 provides the structural means to achieve this integration without increasing manual burden,
417 enabling what Peterson (2008) characterizes as science-based, rather than specification-based,
418 quality assurance.

419 2.4. IMPLICATIONS FOR ARCHITECTURE DESIGN

420 Positioning manufacturing intent as the architectural anchor has direct implications for digital
421 architecture design. Architectures optimized solely for data movement or system interoperability
422 are insufficient; they must also support the definition, instantiation, and governance of intent
423 across systems and lifecycle phases (as illustrated in Figure 2).

424 This requires architectural constructs capable of preserving semantic meaning, binding intent to
425 execution events, and maintaining traceability between design assumptions and operational
426 outcomes. ISA-88 batch control standards provide foundational concepts for structuring
427 manufacturing procedures and equipment relationships (IEC, 2010), while ISA-95 enterprise-
428 control integration models define how manufacturing operations interface with business systems
429 (IEC, 2013). However, neither standard fully addresses the lifecycle persistence of manufacturing
430 intent or the semantic continuity required across development-to-manufacturing transitions.
431 These requirements motivate the need for a persistent architectural foundation—introduced in the
432 next section as the IDDC—that can sustain intent continuity as manufacturing environments evolve,
433 building upon but extending established automation standards.

434 By elevating manufacturing intent from an implicit assumption to an explicit architectural
435 construct, organizations establish a stable reference point for digital execution, quality assurance,
436 and lifecycle learning. This anchor enables the unification of discovery, development, and
437 manufacturing not through uniform tooling, but through a shared and governed understanding of
438 purpose and control.

439 3. THE INTENT-DRIVEN DIGITAL CORE: ARCHITECTURE FOR LIFECYCLE 440 CONTINUITY

441 Having established manufacturing intent as the architectural anchor, the next challenge is
442 preserving that intent as manufacturing systems, sites, and lifecycle phases change. In most digital
443 manufacturing environments, intent is translated repeatedly—into system configurations, data
444 models, and procedural artifacts, each time risking semantic drift or loss of context. Over time, this
445 fragmentation erodes trust in digital systems and increases dependence on manual interpretation.
446 A central limitation of many digital manufacturing initiatives is the implicit assumption that data
447 integration alone is sufficient. Enterprise integration research has long distinguished between
448 syntactic interoperability (the ability to exchange data) and semantic interoperability (the ability to
449 exchange meaning)—with the latter requiring shared conceptual models rather than merely
450 compatible formats (Hohpe & Woolf, 2003; NIST, 2004). In practice, the challenge in manufacturing
451 is not the movement of data, but the persistence of meaning as systems, sites, and lifecycle phases
452 change.

453 To address this challenge, this paper introduces the concept of the Intent-Driven Digital Core
454 (IDDC): a persistent architectural foundation designed to preserve manufacturing intent, execution
455 context, and quality-relevant evidence across the full product lifecycle.

456 The IDDC is not a platform, application, or data repository. Rather, it is an architectural construct
457 that governs how meaning is defined, how execution reality is captured, and how evidence is
458 accumulated and interpreted as manufacturing activities progress from discovery through
459 development, deployment, routine operation, and technology transfer.

460 3.1. WHY "INTENT-DRIVEN" AND WHY "CORE"

461 The Intent-Driven Digital Core is intent-driven because manufacturing outcomes depend
462 fundamentally on preserving the design intent that defines process success. This principle aligns
463 with the digital thread concept articulated by NIST and aerospace manufacturing research: an
464 authoritative, extensible data construct that links product definition, production, and support data
465 across the lifecycle (Hedberg et al., 2017). Scientific understanding, regulatory expectations, and
466 operational experience generate intent that must persist across lifecycle phases. An architecture
467 that fails to explicitly capture and govern this intent forces downstream systems to infer meaning—
468 introducing risk at every handoff, what Grieves and Vickers (2017) characterize as information
469 mirroring failure in digital twin architectures.

470 The architecture is designed to absorb change while preserving semantic continuity. When intent
471 evolves—whether due to improved scientific understanding, operational learning, or site-specific
472 constraints—that evolution is reflected explicitly and traceably, rather than implicitly through
473 disconnected system updates. The IDDC is dynamic in its responsiveness to manufacturing reality,
474 but anchored by intent.

475 It is a core because it underpins all downstream digital capabilities. Advanced analytics, artificial
476 intelligence, digital twins, batch disposition, and technology transfer do not extend the IDDC; they
477 depend on it. This positioning reflects established enterprise architecture principles: Ross et al.
478 (2006) demonstrate that sustainable digital capability requires a foundation for execution—a
479 stable architectural base that enables rather than constrains business agility. Without such a core
480 that preserves intent, downstream capabilities operate on reconstructed or inferred context,
481 limiting scalability, trust, and regulatory confidence.

482 3.2. ARCHITECTURAL SCOPE AND BOUNDARIES

483 The IDDC occupies the space between manufacturing intent and operational execution,
484 complementing established automation standards. ISA-88 (IEC 61512) provides hierarchical
485 models for batch control—procedural elements, equipment entities, and recipe structures—that
486 govern how manufacturing processes are executed (IEC, 2010). ISA-95 (IEC 62264) defines
487 enterprise-control integration, specifying how manufacturing operations interface with business
488 systems through standardized object models (IEC, 2013). The IDDC does not replace these
489 standards or the control systems, manufacturing execution systems, laboratory systems, or quality
490 platforms that implement them. Instead, it provides the semantic and contextual substrate that
491 allows these systems to interoperate without loss of meaning—addressing lifecycle continuity gaps
492 that ISA-88 and ISA-95 were not designed to span.

493 Its scope includes:

- 494 • The formal representation of manufacturing intent and its evolution
- 495 • The binding of intent to execution events as they occur
- 496 • The preservation of context necessary to interpret execution data
- 497 • The accumulation of evidence suitable for quality review, release, and learning

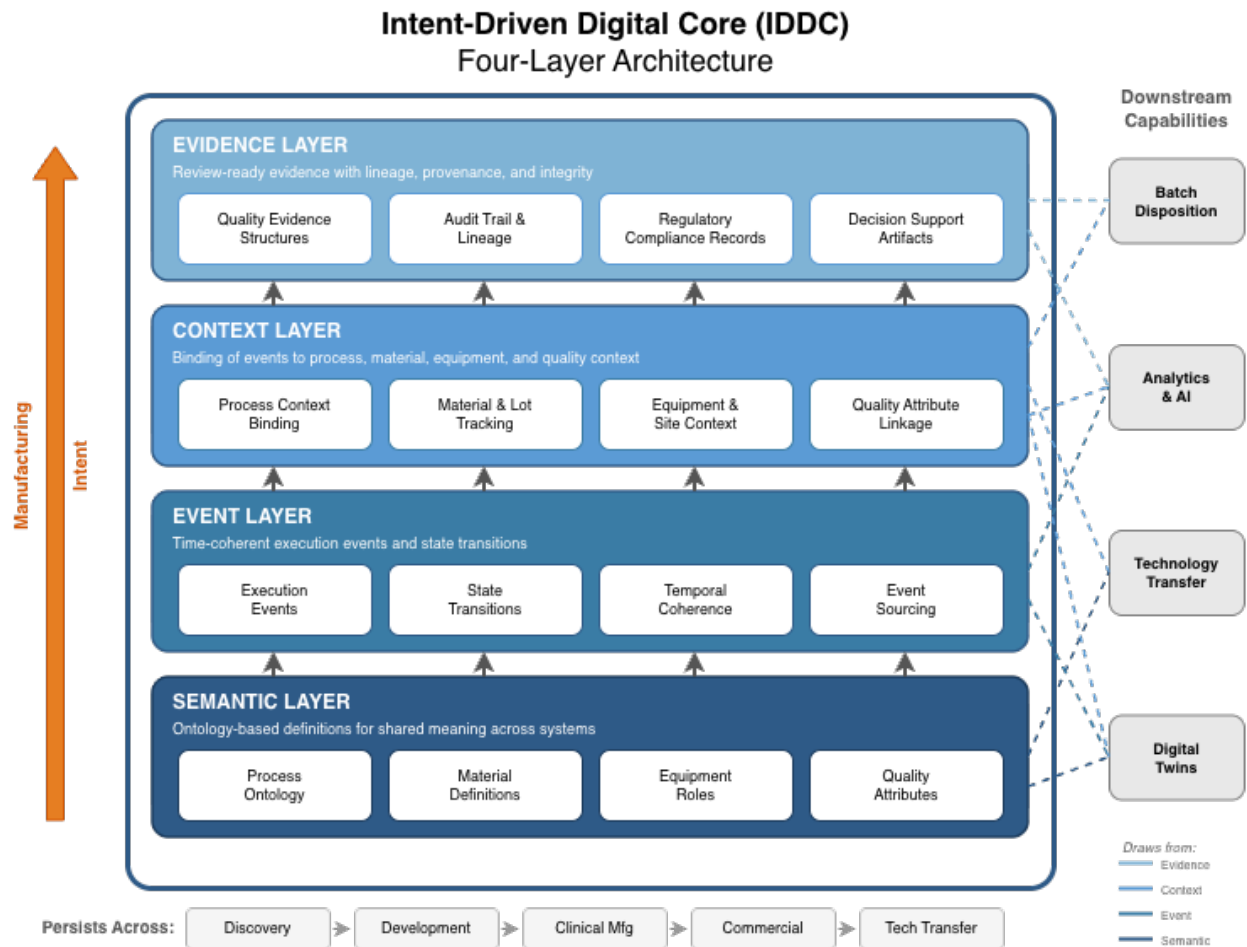

498 Equally important are its boundaries. The IDDC deliberately avoids:

- 499 • Workflow orchestration logic
- 500 • Visualization or analytics presentation layers
- 501 • Tool-specific integration patterns

502 By maintaining these boundaries, the core remains durable even as individual systems are replaced,
503 upgraded, or reconfigured.

504 3.3. CONSTITUENT CAPABILITIES OF THE INTENT-DRIVEN DIGITAL CORE

505 The IDDC comprises four interdependent architectural layers—Semantic, Event, Context, and
 506 Evidence—that together ensure lifecycle continuity (see Figure 2). These layers represent
 507 architectural capabilities rather than discrete technology products; a single platform
 508 implementation might span multiple layers, while distributed implementations might deploy each
 509 layer using specialized tools. What remains constant across implementations is the responsibility
 510 structure: the Semantic Layer must provide shared definitions, the Event Layer must capture time-
 511 coherent execution reality, the Context Layer must bind events to their manufacturing context, and

512 the Evidence Layer must accumulate review-ready quality evidence.

513 Figure 2. The Intent-Driven Digital Core: Four-Layer Architecture enabling lifecycle continuity
 514 through semantic definition, event capture, context binding, and evidence accumulation.

515 As illustrated in Figure 2, these four layers work in concert: the Semantic Layer provides the
 516 vocabulary and relationships that give meaning to manufacturing concepts; the Event Layer
 517 captures what actually happens during execution; the Context Layer binds those events to their
 518 relevant process, material, and equipment context; and the Evidence Layer structures this
 519 contextualized execution data as reviewable evidence. This layered approach ensures that
 520 downstream consumers—whether quality reviewers, analytics systems, or receiving sites during

521 technology transfer—can interpret manufacturing data without reconstructing meaning from
522 fragments.

523 3.3.1.SEMANTIC CAPABILITY

524 At its foundation, the core provides a shared semantic representation of manufacturing intent
525 through formal ontological structures. An ontology, in the information systems sense, is an explicit
526 specification of a conceptualization—a formal representation of entities, relationships, and
527 constraints within a domain (Gruber, 1993). This includes explicit definitions of processes,
528 materials, equipment roles, quality attributes, and their relationships. Industry initiatives such as
529 the Pistoia Alliance CMC Process Ontology and NIIMBL Biopharmaceutical Manufacturing Ontology
530 demonstrate growing consensus that such formal semantic foundations are essential for
531 manufacturing interoperability (Pistoia Alliance, 2023; NIIMBL, 2021). These definitions ensure
532 that systems and stakeholders interpret manufacturing meaning consistently, regardless of where
533 or how execution occurs. (see Figure 4 for the broader ontology landscape)

534 3.3.2.EVENT CAPABILITY

535 Manufacturing execution is inherently event-driven. Fowler (2017) distinguishes three meanings of
536 "event-driven": event notification, event sourcing, and event-based state transfer—each with
537 distinct architectural implications. The IDDC employs event sourcing principles: rather than storing
538 only current state, it captures execution reality as time-aligned events that constitute an append-
539 only log of state transitions (Hohpe, 2006). This preserves the sequence, timing, and conditions
540 under which actions occur, enabling accurate reconstruction of execution history without
541 retrospective inference—a capability essential for regulatory compliance and root-cause analysis.

542 3.3.3.CONTEXT CAPABILITY

543 Events alone are insufficient without context. The ALCOA+ principles—attributable, legible,
544 contemporaneous, original, accurate, complete, consistent, enduring, and available (FDA, 2018)—
545 codify what regulators expect from manufacturing records, and each principle depends on context
546 being bound to data at the point of generation rather than inferred afterward. ISA-95 defines object
547 models for the key manufacturing entities—personnel, equipment, physical assets, and material—
548 that provide the contextual dimensions against which execution must be understood (IEC, 2013).
549 The IDDC extends this approach by binding execution events to relevant process, material,
550 equipment, and —where applicable—patient or lot context at the point of generation. This binding
551 occurs contemporaneously with execution, satisfying the ALCOA+ principle of contemporaneous
552 recording (FDA, 2018). Context binding eliminates the need for downstream systems to infer
553 context after the fact—a common source of data integrity findings in regulatory inspections.

554 3.3.4.EVIDENCE CAPABILITY

555 Quality and compliance depend on evidence, not data volume. The core structures execution
556 outputs as evidence, preserving lineage, provenance, and integrity. This evidence is accumulated
557 continuously and remains directly consumable by quality processes, including batch disposition
558 and regulatory review.

559 Together, these capabilities enable the IDDC to function as a living representation of manufacturing
560 reality, rather than a retrospective record assembled from disparate sources.

561 3.4. LIFECYCLE PERSISTENCE AND CHANGE

562 A defining characteristic of the IDDC is its ability to persist across lifecycle phases without semantic
563 degradation—realizing the digital thread vision of authoritative data continuity from design
564 through production and support (Hedberg et al., 2017). Manufacturing intent defined during

565 development must remain interpretable during site deployment, routine execution, and technology
566 transfer. When changes occur, they are incorporated into the core in a controlled manner that
567 preserves traceability between prior and updated intent, consistent with ICH Q12 principles of
568 established conditions and post-approval change management (ICH, 2019).

569 This persistence supports learning across the lifecycle. Execution outcomes can be evaluated
570 against the intent in effect at the time of manufacture, enabling meaningful comparison, root-cause
571 analysis, and continuous improvement without re-interpretation of historical context— what the
572 NIST smart manufacturing program characterizes as model-based manufacturing intelligence
573 (NIST, 2016).

574 3.5. RELATIONSHIP TO DOWNSTREAM CAPABILITIES

575 The IDDC does not deliver value in isolation. Its purpose is to enable other capabilities to function
576 reliably and at scale.

577 Batch disposition becomes continuous rather than episodic because evidence is accumulated with
578 context by design (Figure 5). Technology transfer becomes repeatable because intent is explicitly
579 encoded and transferable rather than reconstructed (Figure 6). Advanced analytics and AI become
580 credible because they consume semantically stable, contextualized data rather than fragmented
581 proxies.

582 In this way, the IDDC acts as the causal mechanism linking architectural design decisions to
583 operational, quality, and analytical outcomes.

Key Takeaway

The IDDC reframes digital manufacturing architecture around meaning, execution reality, and evidence, rather than data movement alone. By preserving manufacturing intent and context across the lifecycle, it establishes the foundation necessary to unify discovery, development, and manufacturing in a regulated, scalable, and trustworthy manner.

584

585 4. LIFECYCLE DISCONTINUITY FROM DESIGN TO DEPLOYMENT

586 Despite significant advances in digital tooling across the life sciences value chain, most
587 organizations continue to experience pronounced discontinuities as products move from discovery
588 to development and into routine manufacturing. Industry research consistently documents that
589 digital transformation initiatives in pharmaceutical manufacturing fail to achieve stated objectives
590 at rates exceeding 70%, with lifecycle transitions identified as primary failure points (illustrated in
591 Figure 1) (McKinsey & Company, 2016; BioPhorum, 2023). These discontinuities are not limited to
592 system interfaces or data availability; they reflect deeper breaks in how manufacturing intent,
593 context, and accountability are represented and carried forward across lifecycle phases—what
594 knowledge management research characterizes as the challenge of transferring sticky, context-
595 dependent knowledge across organizational boundaries (Argote & Ingram, 2000).

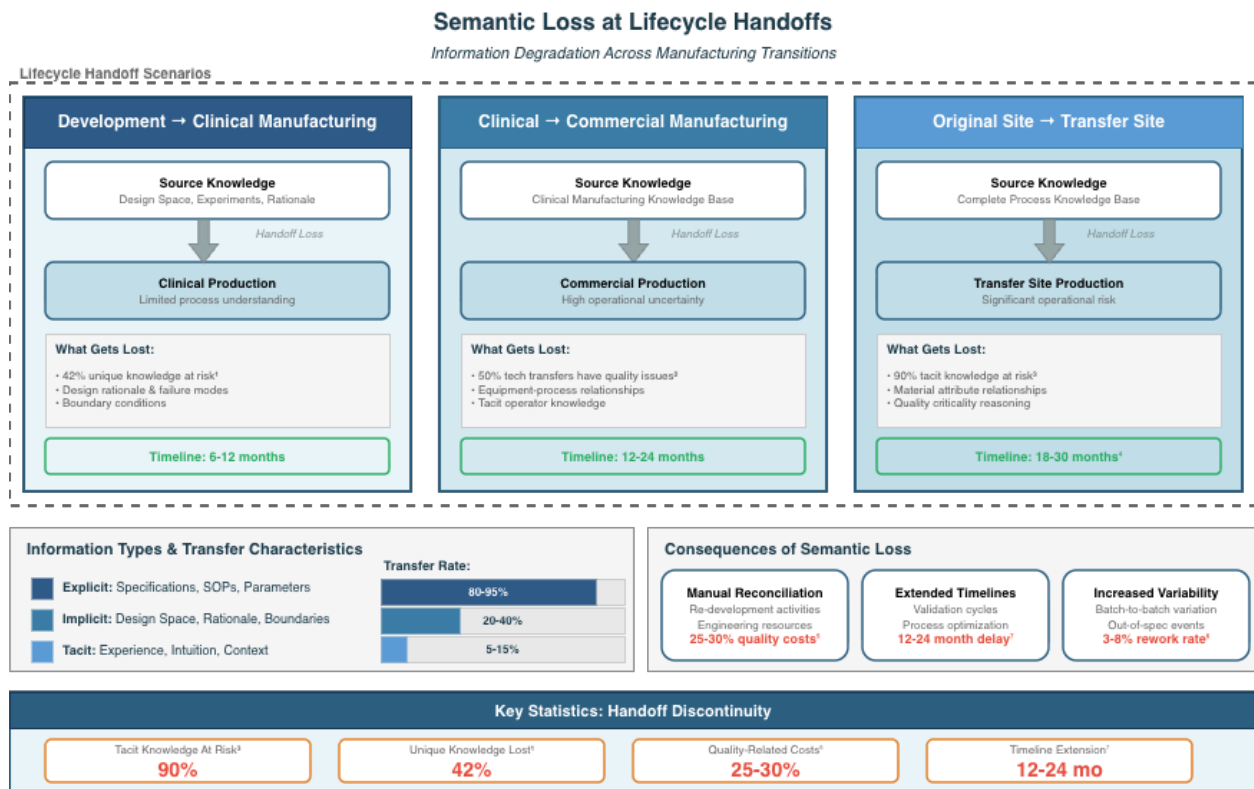

596 During discovery and early development, scientific and process knowledge is generated in
597 environments optimized for exploration and learning. Experimental data, models, and design
598 rationales are created rapidly, often with a high degree of contextual richness but limited formal
599 structure. As products progress toward commercialization, this knowledge must be translated into

600 executable processes, control strategies, and quality expectations suitable for regulated
 601 manufacturing environments. In practice, this translation is rarely continuous.

602 4.1. HANDOFFS AS POINTS OF SEMANTIC LOSS

603 Lifecycle transitions such as scale-up, site deployment, and technology transfer are typically treated
 604 as handoffs between organizational units, systems, or documentation sets. WHO guidance on
 605 technology transfer defines this process as the systematic procedure for transferring documented
 606 knowledge and experience during all phases of development and manufacturing, emphasizing that
 607 transferred knowledge must be sufficient for the receiving unit to understand and apply the
 608 process (WHO, 2011; WHO, 2022). At each handoff, manufacturing intent is partially re-encoded:
 609 design assumptions are summarized, control strategies are simplified, and context is abstracted to
 610 fit the constraints of downstream systems.

611 When intent is not explicitly represented as a lifecycle construct, these handoffs become points of
 612 semantic loss. Critical relationships between process parameters, material attributes, equipment
 613 capabilities, and quality outcomes are weakened or omitted—precisely the process understanding
 614 that Kogut and Zander (1992) characterize as difficult to articulate and transfer because it is
 615 embedded in organizational routines. Downstream teams are then forced to reconstruct meaning
 616 from incomplete artifacts, relying on expert interpretation, informal communication, and
 617 retrospective justification to bridge the gaps. Figure 3 visualizes this semantic loss pattern across

Sources: ¹Panopto Workplace Report; ²CDMO Live 2025; ³Wah (1999), Bonner (2000); ⁴McKinsey (2020); ⁵McKinsey POBOS; ⁶McKinsey POBOS (3-8% rework); ⁷ISPE (2018)

618 typical lifecycle handoffs.

619 Figure 3. Semantic Loss at Lifecycle Handoffs: Knowledge types, transfer rates, and organizational consequences.

620 Figure 3 highlights three critical handoff scenarios—development to clinical, clinical to commercial,
621 and original site to transfer site—where semantic loss characteristically occurs. The figure
622 distinguishes between explicit information (specifications, SOPs, batch records) that typically
623 transfers successfully, implicit knowledge (design space, control strategy rationale) that is often
624 weakened, and tacit expertise (troubleshooting experience, process intuition) that rarely survives
625 transfer. Industry data confirms the consequences: knowledge gaps—rather than purely technical
626 issues—are widely identified as a leading cause of extended transfer timelines. The IDDC addresses
627 this by making implicit knowledge explicit through ontological representation and by capturing
628 tacit expertise as contextualized execution patterns.

629 This pattern is especially evident in multi-site and external manufacturing networks, where
630 differences in equipment, systems, and local practices amplify the effects of incomplete or
631 ambiguous intent transfer. ISPE technology transfer guidance documents that receiving sites
632 routinely require 12-24 months to achieve comparable process performance, with knowledge gaps
633 and context loss identified as primary contributors to extended timelines (ISPE, 2018). The result is
634 increased variability, longer startup timelines, and greater reliance on tacit knowledge held by a
635 small number of individuals—a fragile dependency that BioPhorum identifies as a critical barrier to
636 manufacturing network scalability (BioPhorum, 2020).

637 The author's experience confirms this pattern. When introducing a cell therapy
638 manufacturing process to SCADA-augmented production, the team required
639 nine months from initial engagement to detailed design. This included over
640 one hundred hours of requirements workshops, a three-day intensive cross-
641 functional session to define the process flow at major unit operation level, and
642 two additional weeks of detailed design interviews. The discovery was
643 humbling: beyond reading through batch records, there was limited structured
644 understanding of how the process actually functioned. Multiple clinical
645 process versions existed—with no mapping of how one version had derived
646 from another or why changes had been made. Even after implementation
647 partners produced painstakingly detailed graphical process flow diagrams,
648 workshop participants continued to identify inaccuracies, local variations, and
649 anticipated future changes. The knowledge existed, but it was distributed
650 across individuals, embedded in practice, and never captured in a form that
651 could be transferred without extensive person-to-person reconstruction. A
652 well-constructed, intent-driven digital architecture would have substantially
653 reduced this discovery burden—not by eliminating workshops entirely, but by
654 bringing structured process knowledge, version lineage, and design rationale
655 to inform the conversation from the start.

656 A related pattern is observable when products launch into manufacturing without a structured
657 intent record. In one observed instance involving multiple concurrent product launches at a
658 clinical-stage manufacturer, process characterization records were incomplete, control strategies
659 were undocumented, and the rationale for key equipment selections and process design decisions
660 existed only in the knowledge of individual subject matter experts distributed across departments.
661 When those experts were unavailable, manufacturing and engineering teams were forced to
662 reconstruct intent through ad hoc cross-departmental conversations — a process that introduced
663 delays, risked misinterpretation, and could not withstand regulatory scrutiny. When process
664 changes were needed to accommodate clinical or commercial realities, the absence of a
665 documented intent record meant that each change required de novo justification rather than

666 traceable departure from an established baseline. An intent-driven architecture, had it been in place
667 from early development, would have provided the structured rationale, the evidence of original
668 design decisions, and the traceability to demonstrate that changes preserved the intended outcome
669 — exactly the defensibility that investigators and auditors require under ICH Q10 and Q12.

670 4.2. FRAGMENTATION ACROSS SYSTEMS AND FUNCTIONS

671 Lifecycle discontinuity is further reinforced by functional and system silos. Discovery, development,
672 manufacturing, and quality organizations often operate distinct digital ecosystems, each optimized
673 for local objectives and constraints. While integration efforts may connect these systems at a
674 technical level, they rarely ensure continuity of meaning.

675 As a consequence, the same manufacturing concepts such as a critical process parameter or quality
676 attribute may be represented differently across systems, with no authoritative source of truth.
677 ISA-95 (IEC 62264) defines standard object models for manufacturing operations, yet
678 implementations frequently diverge in how these models are instantiated locally, creating semantic
679 heterogeneity despite nominal standards compliance (IEC, 2013). Temporal misalignment between
680 data sources compounds the problem, making it difficult to establish a coherent view of execution
681 reality. Over time, digital systems become sources of data, but not of shared understanding—a
682 condition that NIST semantic interoperability research identifies as the core barrier to
683 manufacturing system integration (NIST, 2006).

684 This fragmentation shifts effort away from value-adding activities toward reconciliation. Engineers,
685 operators, and quality reviewers spend significant time assembling, validating, and interpreting
686 information rather than evaluating performance or managing risk. While this manual effort often
687 succeeds in the short term, it does not scale as product portfolios and manufacturing networks
688 grow.

689 4.3. CONSEQUENCES FOR QUALITY, TRANSFER, AND INSIGHT

690 The impact of lifecycle discontinuity is most visible in areas that depend on continuity by design.

691 In batch disposition, evidence required for release is frequently assembled after execution from
692 multiple systems, each with its own assumptions and context. Review effort increases as reviewers
693 must reconstruct what occurred, under what conditions, and whether intent was met. This episodic
694 approach places a heavy cognitive burden on quality organizations and limits opportunities for
695 earlier risk identification.

696 In technology transfer, the absence of digitally transferable intent forces each receiving site to
697 reinterpret process understanding and quality expectations. ICH Q5E establishes that
698 manufacturing process changes—including site transfers—require demonstration of comparability
699 to ensure product quality, safety, and efficacy are maintained (ICH, 2004). Even when
700 documentation is complete, differences in execution context and system representation require
701 local adaptation, extending timelines and introducing variability. Scale-up and transfer research
702 documents that process understanding losses during technology transfer contribute significantly to
703 manufacturing deviations in the first 12-18 months of commercial production (Farid, 2007; Garcia-
704 Aponte et al., 2017).

705 In advanced analytics and AI, fragmented semantics and inconsistent context undermine trust.
706 Models trained on data that lacks stable meaning or provenance struggle to generalize across sites
707 or time, reinforcing skepticism and limiting adoption beyond exploratory use cases.

708 Across these domains and others, organizations compensate for architectural gaps through
709 increased oversight, manual controls, and localized expertise. While effective in regulated

710 environments, these compensatory mechanisms constrain scalability and slow the realization of
711 digital value.

712 4.4. ARCHITECTURAL ROOTS OF DISCONTINUITY

713 Crucially, these challenges do not arise from poor execution or insufficient digital investment. They
714 stem from architectures that were not designed to preserve intent, context, and evidence across the
715 lifecycle. Enterprise architecture research demonstrates that sustainable digital capability requires
716 designing for integration from the outset, treating data and meaning as shared enterprise assets
717 rather than application-specific resources (Ross et al., 2006). When digital systems are
718 implemented as phase-specific solutions optimized for local objectives, continuity becomes an
719 operational burden rather than an architectural property.

720 Without a persistent architectural construct to anchor manufacturing intent and bind it to
721 execution reality, continuity must be recreated repeatedly through people and process. This
722 approach is inherently fragile and increasingly unsustainable as manufacturing complexity grows.

723 Addressing lifecycle discontinuity therefore requires more than improved integration or
724 documentation. It requires an architectural foundation capable of maintaining semantic continuity
725 as products, sites, and systems evolve. The following sections examine how such an architecture is
726 enabled—through explicit semantic constructs, socio-technical alignment, and lifecycle-aware
727 governance—and how its effectiveness can be evaluated through outcomes such as batch
728 disposition, technology transfer, and advanced analytics.

Key Takeaway

Lifecycle discontinuity manifests not as missing data but as lost meaning—semantic loss at handoffs, fragmented context across systems, and reconstructed (rather than transferred) process understanding. These patterns are architectural in origin and cannot be resolved through improved documentation or integration alone.

729 5. ONTOLOGY AS A CONTRACT OF MEANING

730 The lifecycle discontinuities described in the previous section arise not from a lack of data, but from
731 the absence of a shared, durable understanding of what that data represents. When manufacturing
732 systems exchange information without a common semantic foundation, continuity of intent cannot
733 be assumed. Instead, meaning must be inferred, reconciled, or reinterpreted (often manually) at
734 each lifecycle transition.

735 To address this challenge, digital architectures must incorporate an explicit mechanism for defining
736 and governing meaning. In this context, ontology is not an academic abstraction, but a practical
737 architectural construct: a contract of meaning that ensures manufacturing intent, execution context,
738 and quality evidence are interpreted consistently across systems, sites, and lifecycle phases.

739 5.1. ONTOLOGY AS AN ARCHITECTURAL, NOT ACADEMIC, CONSTRUCT

740 In manufacturing environments, the term “ontology” is often associated with knowledge graphs or
741 formal logic models. While these techniques can be valuable, the architectural role of ontology is
742 more fundamental. An ontology defines the entities, roles, relationships, and constraints that give
743 data its meaning within a specific domain.

744 In an intent-driven digital architecture, ontology serves as the authoritative reference for:

- 745 • What constitutes a process, material, equipment role, or quality attribute
746 • How these elements relate to one another
747 • How changes to one element affect interpretation of others

748 This semantic contract allows systems to exchange information without embedding meaning
749 directly into point-to-point integrations or local data models. Instead, meaning is externalized,
750 governed, and reusable.

751 5.2. FROM DATA INTEGRATION TO SEMANTIC INTEROPERABILITY

752 Traditional system integration focuses on syntactic compatibility, ensuring that data can be
753 transmitted and stored. While necessary, this approach does not guarantee that data will be
754 interpreted consistently. As a result, the same concept may appear under different names,
755 structures, or assumptions across systems, reinforcing the fragmentation described in Section 4.

756 Ontology enables semantic interoperability by decoupling meaning from system implementation.
757 When systems reference shared semantic definitions, they no longer need to encode local

This shift from data integration toward semantic interoperability is already reflected in emerging industry initiatives. The Pistoia Alliance CMC Process Ontology extends established manufacturing frameworks (specifically ISA-88 and ISA-95) by defining shared semantic representations of processes, parameters, and manufacturing stages across chemical and biologic modalities.

NIIMBL, in collaboration with the OAGi, has released biopharmaceutical manufacturing ontologies to harmonize representations of concepts across the value chain. These life-science-specific efforts align with broader industrial ontology work led by NIST through initiatives such as the Industrial Ontologies Foundry (IOF), which provide reference models and design patterns for manufacturing-domain semantic frameworks. Collectively, these initiatives reflect an industry-wide recognition that scalable interoperability depends on shared meaning, not merely connected systems. Figure 4 illustrates this ontology landscape, showing how foundational standards build toward domain-specific applications.

758 interpretations of manufacturing concepts. This is particularly important in regulated
759 environments, where consistency of interpretation underpins quality, compliance, and trust.

760 Established manufacturing frameworks, such as ISA-95 and related object models, provide a useful
761 starting point by defining common abstractions for equipment, materials, and processes. However,
762 these frameworks must often be extended to reflect modality-specific requirements, complex
763 material genealogy, and evolving process understanding. Ontology provides the mechanism to
764 formalize and govern these extensions without fragmenting the underlying architecture.

765 5.3. FROM SEMANTIC DEFINITION TO OPERATIONAL DEPLOYMENT

766 The preceding discussion establishes what ontology provides architecturally—a governed,
767 externalized contract of meaning that enables semantic interoperability across systems and
768 lifecycle phases. A complementary question, less frequently addressed in the literature, concerns
769 what ontology demands of the systems and organizations that deploy it: where does it reside, how
770 do operational systems consume it, and through what mechanisms do semantic definitions
771 translate into executable, traceable manufacturing operations?

772 A proposed deployment architecture addressing these questions is developed in Appendix B, using
773 cell and gene therapy (CGT) manufacturing as a bounded scope. The architecture describes six
774 layers through which ontological relationships are realized in practice: governed ontology
775 definition, ontology access and distribution infrastructure, MES instantiation aligned with ISA-95
776 structural objects, integration-layer contextualization, data platform materialization, and
777 consumption by quality and analytical processes. Of particular practical significance is the access
778 layer—the mechanism by which consuming systems reference, bind to, and stay synchronized with
779 the governed ontology—which addresses the fundamental deployment question of where the
780 ontology resides and how systems ensure they operate against the current semantic version. The
781 central architectural principle is that ontology functions as a governed semantic backbone—
782 systems map to it rather than execute it—with ISA-95 providing structural execution models and
783 ontology supplying the meaning, roles, and traceability that make execution data interpretable
784 across boundaries.

785 CGT manufacturing was selected as the stress-test context because it intensifies every dimension of
786 the deployment problem. Autologous therapies demand mandatory lot genealogy, non-collapsible
787 lineage, patient linkage as a first-class semantic construct, and disposition semantics that apply to a
788 specific patient’s therapy rather than a statistical population of product units. The ontology
789 deployment architecture that satisfies these requirements inherently accommodates less
790 demanding modalities—establishing CGT as a rigorous validation boundary for the IDDC’s Semantic
791 Layer.

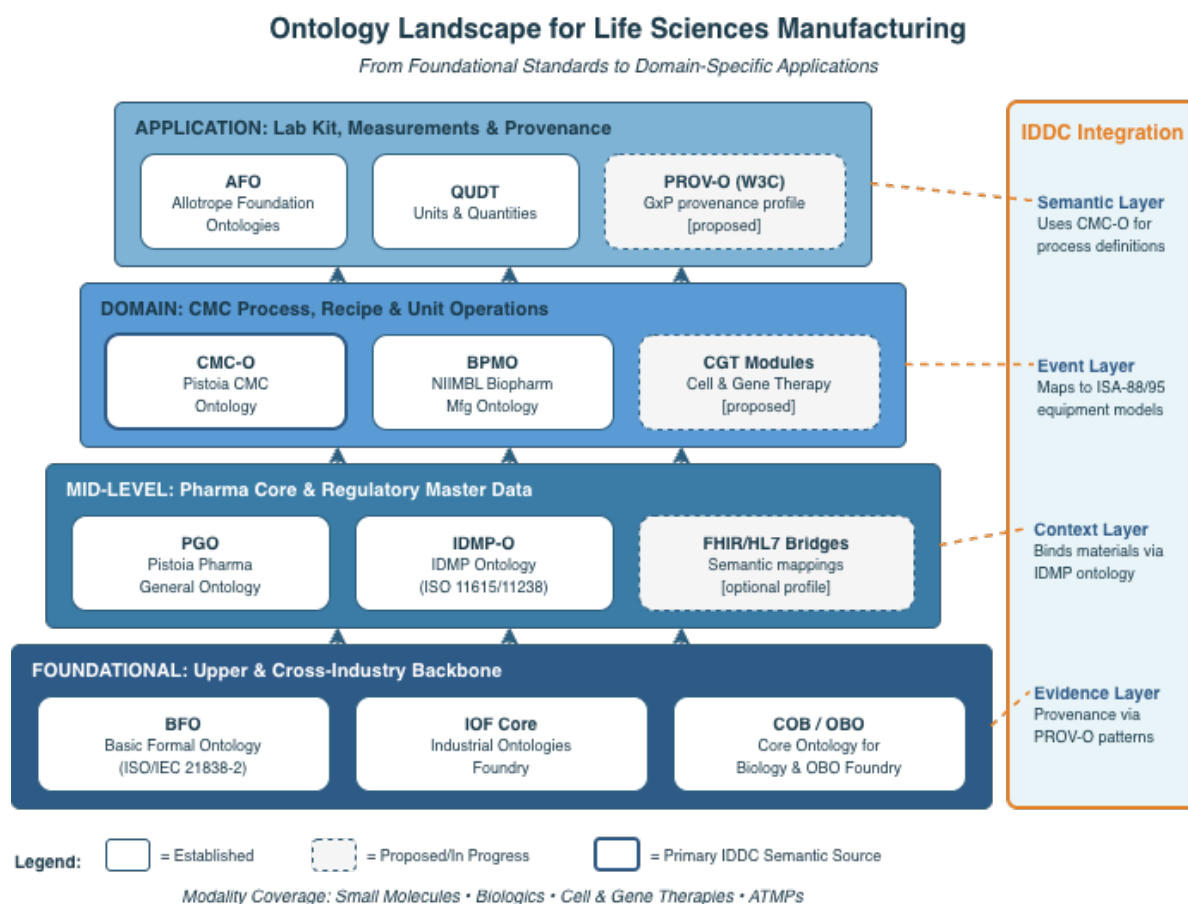

792 It should be noted that this deployment architecture represents a design science artifact: a
793 proposed solution validated by alignment with international standards (ISA-95, ISA-88, BFO, IOF
794 Core) and consortium consensus (Pistoia Alliance, NIIMBL), rather than a validated
795 implementation. The biopharmaceutical industry does not yet have a published example of end-to-
796 end ontology deployment in manufacturing. The contribution is the architecture itself—providing
797 an engineering blueprint grounded in the ontology landscape described above and the standards
798 ecosystem that governs it.

799 5.4. ROLE OF ONTOLOGY IN PRESERVING MANUFACTURING INTENT

800 Manufacturing intent, as defined in Section 2, cannot persist across the lifecycle unless its meaning
801 is explicit and interpretable. Ontology enables this by formally encoding the relationships that
802 define intent; for example, how a critical process parameter relates to a quality attribute, or how an
803 equipment role constrains execution conditions.

804 When intent is instantiated in execution systems, ontology ensures that execution events are
805 interpreted in the correct semantic context (the Semantic Layer shown in Figure 2). This eliminates
806 the need for downstream systems or reviewers to infer intent from isolated data points. Instead,
807 execution data is inherently meaningful because it is generated and consumed within a shared
808 semantic framework.

809 Internal and external ontology initiatives provide the semantic foundation required to preserve
 810 manufacturing intent across lifecycle phases, enabling design assumptions, execution reality, and
 811 quality evidence to remain coherently linked as processes scale, transfer, and evolve.

812 Figure 4. Ontology Landscape: Foundational to Domain-Specific for Life Sciences Manufacturing. The CMC Process Ontology (CMC-O)
 813 provides the primary semantic foundation for the IDDC Semantic Layer.

814 5.5. ONTOLOGY AS AN ENABLER OF EVIDENCE AND TRUST

815 Quality decisions depend not only on data availability, but on confidence in how that data was
 816 generated and what it represents. Ontology contributes directly to this confidence by providing
 817 traceable, governed definitions of meaning that persist over time.

818 When execution data and contextual information are linked through shared semantic constructs,
 819 evidence accrues as execution unfolds rather than being reconstructed after the fact. Reviewers can
 820 evaluate outcomes against the intent in effect at the time of manufacture, with clear lineage
 821 between design assumptions, execution events, and quality conclusions.

822 This semantic stability also underpins trust in advanced analytics and AI. Models trained on data
 823 that is semantically consistent and contextually bound are more likely to generalize across sites and
 824 time, reducing skepticism and enabling broader adoption.

825 5.6. GOVERNANCE OF MEANING ACROSS THE LIFECYCLE

826 Because ontology defines meaning, it must be governed with the same rigor applied to other
827 lifecycle assets. Changes to semantic definitions, whether driven by new process understanding,
828 operational learning, or regulatory feedback, must be deliberate, versioned, and traceable.

829 This governance does not imply centralized control of all systems, but it does require clear
830 ownership of semantic constructs and disciplined change management. Without such governance,
831 ontologies risk fragmenting in the same way as ungoverned data models, undermining their
832 architectural value.

833 When properly governed, ontology becomes the connective tissue between intent, execution, and
834 evidence—enabling the IDDC to function as designed.

Key Takeaway

Ontology provides the semantic contract that allows manufacturing intent to be interpreted consistently across systems, sites, and lifecycle phases. By externalizing and governing meaning, ontology transforms digital integration from data exchange into true lifecycle interoperability—enabling continuity, trust, and scalability in regulated manufacturing environments.

835

836 6. EVENT, CONTEXT, AND EVIDENCE BY DESIGN

837 Digital manufacturing architectures often treat execution data as a byproduct of system operation
838 rather than as a primary architectural concern. Data is captured because systems generate it, not
839 because it has been intentionally designed to serve downstream interpretation, quality decisions, or
840 lifecycle learning. As a result, execution records are frequently incomplete, temporally misaligned,
841 or insufficiently contextualized to support confident decision-making without manual
842 reconstruction. Regulatory expectations for data integrity (FDA, 2018; MHRA, 2018; PIC/S, 2021)
843 increasingly require that manufacturing records be attributable, contemporaneous, and complete at
844 the point of generation—requirements that retrospective assembly inherently struggles to satisfy.
845 These requirements align with the ALCOA+ framework, which has become the de facto standard for
846 data integrity expectations across global regulatory authorities.

847 An intent-driven digital architecture requires a different approach. Rather than asking how data can
848 be collected and integrated after execution, it must be designed so that events, context, and
849 evidence are bound together at the point of execution, by design.

850 6.1. MANUFACTURING EXECUTION AS AN EVENT-DRIVEN REALITY

851 Manufacturing is inherently event-driven. Actions occur in time, under specific conditions,
852 involving defined materials, equipment, and process states. Fowler (2017) distinguishes three
853 architectural patterns for event-driven systems—event notification, event-carried state transfer,
854 and event sourcing—each with different implications for how execution history is preserved and
855 replayed. However, many digital systems still represent execution primarily as time-series data
856 streams or aggregated records, detached from the events that give them meaning.

857 When execution is treated as a sequence of discrete, time-aligned events (rather than as isolated
858 measurements), what occurred, when it occurred, and under what conditions becomes explicit
859 rather than inferred. This event-centric representation enables accurate reconstruction of

860 execution history without reliance on retrospective interpretation or manual correlation across
861 systems.

862 Designing for events does not require replacing existing control or execution systems. It requires
863 ensuring that execution data is captured and structured in a way that reflects the actual sequence
864 and state transitions that matter for process understanding and quality assessment.

865 This distinction does not diminish the value of high-frequency, time-series data at the point of
866 generation. Detailed signal-level data remains essential for real-time monitoring, control, and
867 engineering troubleshooting, where fine-grained temporal resolution enables rapid diagnosis of
868 equipment behavior and process dynamics. However, not all time-series data needs to propagate
869 unchanged through downstream systems. As execution data moves beyond local operational
870 contexts, temporal coherence and contextual relevance become more important than raw
871 resolution. Event-based abstractions allow downstream consumers to interpret execution
872 outcomes accurately without carrying the full burden of signal-level detail that is meaningful
873 primarily at the point of execution. This layered approach aligns with Hohpe and Woolf's (2003)
874 principle that integration architectures should transform data to match consumer needs rather
875 than propagating raw operational detail.

876 6.2. CONTEXT BINDING AT THE POINT OF EXECUTION

877 Events alone are insufficient without context. The same action or measurement can have different
878 significance depending on the process step, material state, equipment role, or control strategy in
879 effect at the time. When context is not bound at execution, downstream systems and reviewers
880 must infer it after the fact, often with incomplete information.

881 An intent-driven architecture binds context to execution events at the point of generation, using the
882 shared semantic constructs established through ontology as shown in the Context Layer of Figure 2.
883 This includes, at minimum:

- 884 • Process context (step, phase, or operation)
- 885 • Material context (lot, batch, or patient linkage where applicable)
- 886 • Equipment context (role, configuration, or capability)
- 887 • Quality context (applicable limits, specifications, or control strategies)

888 By binding this context explicitly, execution data becomes immediately interpretable. Downstream
889 consumers no longer need to reconstruct meaning from timestamps, system identifiers, or
890 procedural assumptions. This design directly supports the expectations of 21 CFR Part 11 and EU
891 GMP Annex 11 (European Commission, 2011), which require that electronic records be complete,
892 accurate, and readily retrievable throughout their retention period.

893 6.3. FROM DATA CAPTURE TO EVIDENCE GENERATION

894 Quality and compliance decisions depend on evidence, not raw data. The FDA's process validation
895 guidance (FDA, 2011) and ICH Q10 (ICH, 2008) both emphasize that quality assurance depends on
896 contemporaneous, contextually complete records that demonstrate process understanding and
897 control—precisely the characteristics that distinguish evidence from mere data capture. Evidence is
898 data that has been contextualized, attributed, and structured to support an explicit claim such as
899 conformance to intent, suitability for release, or identification of risk. Evidence generation, as
900 opposed to process data generation (see Figure 5 for how this enables continuous disposition),
901 therefore depends not on preserving all execution data at its highest resolution, but on preserving
902 the right abstractions of execution aligned to manufacturing intent.

903 In many manufacturing environments, evidence is assembled retrospectively. Execution data is
904 extracted from multiple systems, aligned manually, and reviewed against expectations after the
905 fact. This episodic approach increases review burden and limits opportunities for early detection of
906 deviations or emerging trends.

907 A contrasting architectural approach is demonstrated by an alarm management platform
908 implemented at a cell therapy manufacturing organization (see Appendix A). Prior to
909 implementation, alarms generated across diverse equipment types accumulated in individual
910 systems, each with its own interface and storage approach. When alarms were logged by operators,
911 they were typically reviewed only when a deviation triggered an investigation—a pattern common
912 across the industry given resource constraints, but one that creates temporal disconnect between
913 alarm occurrence and quality assessment. In autologous therapies, where one batch represents one
914 patient, the consequences of delayed alarm visibility extend beyond operational metrics to direct
915 patient impact.

916 The platform architecture explicitly addresses the Event, Context, and Evidence layers of the IDDC
917 framework. The Event Layer captures alarms with their equipment, process, and batch
918 relationships. The Context Layer binds human interpretation—documenting causation, treatment,
919 and impact assessment—contemporaneously with execution. The Evidence Layer produces
920 structured output including alarm lineage, audit trail, and the decision framework supporting batch
921 disposition. This progressive evidence accumulation enables the continuous disposition model
922 described in Section 8, while the platform’s extensible architecture provides a foundation for the
923 AI-assisted capabilities discussed in Section 10.

924 Designing for evidence generation changes this dynamic. When events and context are captured
925 together, evidence can be accumulated progressively and continuously as execution occurs.
926 Lineage, provenance, and integrity are preserved by design, reducing reliance on manual
927 reconciliation and enabling earlier, more focused quality oversight. PIC/S guidance on data
928 management and integrity (PIC/S, 2021) explicitly recognizes that data governance embedded in
929 system design is more robust than procedural controls applied after the fact.

930 6.4. TEMPORAL COHERENCE AND TRACEABILITY

931 A common failure mode in digital manufacturing is temporal incoherence: data streams that cannot
932 be reliably aligned in time or attributed to the correct execution state. This undermines traceability
933 and erodes trust in digital records. EU GMP Annex 11 (European Commission, 2011) requires that
934 audit trails record time-stamped, operator-attributed changes to electronic records—a
935 requirement that presupposes the temporal coherence that many manufacturing data architectures
936 fail to provide.

937 An event-centric, context-bound architecture enforces temporal coherence by anchoring all
938 execution data to a common event timeline. This allows design intent, execution reality, and quality
939 outcomes to be evaluated in relation to one another without ambiguity.

940 Traceability, in this model, is not achieved through exhaustive logging alone, but through structured
941 relationships between intent, events, and evidence. This approach supports both regulatory
942 expectations for traceable, attributable records (FDA, 2018; PIC/S, 2021) and operational learning
943 without excessive data overhead.

944 6.5. ARCHITECTURAL IMPLICATIONS

945 Designing for event, context, and evidence has several important architectural implications:

- 946 • Execution systems must expose meaningful events, not just signals, following event-driven
947 patterns appropriate to the integration context (Fowler, 2017; Hohpe & Woolf, 2003)
- 948 • Semantic definitions must be available at execution time, not applied later, consistent with
949 the ontological access architecture described in Section 5
- 950 • Data pipelines must preserve event ordering and contextual relationships, ensuring
951 temporal coherence as required by 21 CFR Part 11 and EU GMP Annex 11 (European
952 Commission, 2011)
- 953 • Evidence generation must be treated as a first-class architectural outcome

Key Takeaway

Event-driven execution, contextual binding, and evidence generation are not downstream analytics concerns; they are architectural design choices. When these elements are designed together, manufacturing data becomes inherently meaningful, reviewable, and reusable across the lifecycle. When they are not, organizations are forced to compensate through manual interpretation and retrospective reconstruction.

954 7. PEOPLE AS AN ARCHITECTURAL DEPENDENCY

955 Digital architecture determines not only how information flows, but also who interprets, owns, and
956 acts on manufacturing intent as it evolves across the lifecycle. As scientific understanding is
957 translated into executable processes and quality decisions, architecture shapes where meaning is
958 preserved, where judgment is applied, and where responsibility resides. As architectures evolve
959 from isolated systems toward intent-driven, lifecycle-aware foundations, the role of people shifts
960 accordingly. In this context, people are not external users of digital systems; they are integral
961 components of the design itself. This perspective aligns with socio-technical systems theory (Trist &
962 Bamforth, 1951), which demonstrates that technical and social subsystems must be jointly
963 optimized—optimizing one at the expense of the other produces suboptimal outcomes regardless
964 of the sophistication of either component.

965 When architectural design fails to account for human roles, decision rights, and capabilities,
966 continuity cannot be sustained. Meaning is reintroduced informally, intent is reinterpreted locally,
967 and the fragmentation described in earlier sections reappears despite technical integration.

968 7.1. WHY DIGITAL ARCHITECTURE REDEFINES ROLES

969 Traditional manufacturing organizations evolved around system and functional boundaries.
970 Automation, manufacturing execution, quality systems, and enterprise platforms were
971 implemented and governed independently, with human roles focused on system ownership and
972 reconciliation. Digital maturity was measured by system availability and compliance rather than by
973 continuity of meaning across the lifecycle. Conway's (1968) observation that organizations design
974 systems mirroring their communication structures explains why: when organizational boundaries
975 align with system boundaries rather than with lifecycle flows, the resulting architectures inevitably
976 fragment meaning at each handoff.

977 An intent-driven digital architecture fundamentally alters this dynamic in three ways.

978 First, it drives a shift from system ownership to intent ownership. When manufacturing intent is
979 explicitly defined and preserved across lifecycle phases, accountability naturally moves toward
980 those responsible for defining, maintaining, and governing that intent, rather than those operating
981 individual systems. This represents a shift from what Mintzberg (1979) characterizes as machine

982 bureaucracy—organized around functional specialization—toward a more integrative structure
983 where coordination mechanisms cut across traditional departmental boundaries.

984 As a result, human effort shifts decisively from manual reconciliation of fragmented records toward
985 informed judgment under uncertainty, where manufacturing context is preserved and intent is
986 explicit by architectural design.

987 Second, it collapses traditional IT, OT, and Quality boundaries. Semantic consistency, event
988 coherence, and continuous evidence generation require cross-functional collaboration by design.
989 Architectural separation between these domains becomes a source of risk rather than protection.

990 Third, it increases reliance on human judgment over manual reconciliation. As execution data
991 becomes contextualized and evidence is accumulated progressively, people spend less time
992 assembling information and more time evaluating uncertainty, risk, and deviation significance. This
993 sets the stage for what Malone (2018) describes as collective intelligence: human-machine
994 collaboration in which AI handles routine pattern recognition and evidence assembly while humans
995 exercise judgment on significance, risk, and response—a partnership that produces outcomes
996 neither could achieve independently.

997 Architecture, in this sense, does not remove people from the process. It elevates the nature of
998 human contribution and increases impact.

999 7.2. CAPABILITY-BASED ROLES ENABLED BY THE ARCHITECTURE

1000 As the IDDC becomes the organizing foundation, certain capabilities become architecturally
1001 necessary. These should be understood as functional roles rather than prescriptive job titles,
1002 consistent with the capability-based organizational models advocated by the ISPE Pharma 4.0
1003 Operating Model (ISPE, 2019) and Galbraith's (2014) framework for designing organizations
1004 around strategic capabilities rather than hierarchical structures.

1005 7.2.1. MANUFACTURING INTENT OWNER

1006 Accountable for defining and stewarding manufacturing intent across lifecycle phases, including
1007 process objectives, constraints, and quality expectations. This role ensures semantic continuity
1008 from development through routine manufacture and transfer.

1009 7.2.2. DATA PRODUCT OWNER

1010 Responsible for reusable, governed manufacturing data assets that serve multiple consumers,
1011 including operations, quality, analytics, and AI. The emphasis is on lifecycle fitness, lineage, and
1012 interpretability rather than local optimization.

1013 7.2.3. DIGITAL TECHNOLOGY TRANSFER LEAD

1014 Bridges development, manufacturing, and quality to ensure that intent, context, and evidence are
1015 digitally transferable across sites and partners without semantic reinterpretation (see Figure 6).

1016 7.2.4. DATA STEWARD

1017 Ensures that execution evidence generated by the architecture is complete, trustworthy, and
1018 suitable for continuous disposition and regulatory review, with explicit focus on provenance and
1019 traceability.

1020 7.2.5. MANUFACTURING SYSTEMS ARCHITECT

1021 Designs execution and integration models that preserve intent and context across control systems,
1022 MES, and data platforms, ensuring architectural consistency as systems evolve.

1023 These capabilities may be distributed across multiple individuals or embedded within existing
1024 roles. What matters is that the capability exists and is explicitly recognized.

1025

The roles described above are intentionally framed as architectural capabilities rather than prescriptive job titles. They align closely with established competency frameworks such as those promoted by the International Association of Automation Engineers (IAAE) and smart manufacturing personas defined by CESMII, while operating at a higher level of abstraction. This positioning allows organizations to map these capabilities onto existing roles and career pathways without mandating structural reorganization, while still ensuring that critical ownership of intent, data, and evidence is explicitly addressed.

1026

1027 7.3. UPSKILLING REQUIREMENTS ACROSS THE ORGANIZATION

1028 An intent-driven architecture changes not only roles, but also the skills required to operate
1029 effectively within it.

1030 For frontline operators, the emphasis shifts toward:

- 1031 • Interpreting contextualized digital records rather than transcribing data
- 1032 • Understanding how execution actions contribute to downstream evidence
- 1033 • Confident interaction with digital batch records and contextual views

1034 For engineers and technical specialists, required skills increasingly include:

- 1035 • Ontology-aware process and system design
- 1036 • Event-driven architectural thinking
- 1037 • Designing for reuse, transferability, and lifecycle persistence

1038 For quality professionals, the architecture enables and demands a transition toward:

- 1039 • Continuous disposition models
- 1040 • Data-driven risk assessment
- 1041 • Evaluation of uncertainty rather than completeness alone

1042 These changes reinforce that digital transformation is not an add-on training exercise, but a
1043 redefinition of professional practice within manufacturing. Kotter (1996) identifies the failure to
1044 anchor change in organizational culture as the most common reason transformation initiatives
1045 regress; in this context, upskilling must be accompanied by changes in performance expectations,
1046 career incentives, and operational workflows to sustain the architectural shift.

1047 7.4. ORGANIZATIONAL IMPLICATIONS

1048 Architectural continuity requires organizational alignment. Ownership of intent must be explicit
1049 and cross-functional, spanning development, manufacturing, quality, and digital functions.

1050 Galbraith (2014) demonstrates that organizations pursuing lateral integration require explicit
1051 coordination mechanisms—shared goals, liaison roles, and integrative processes—that go beyond

1052 structural reorganization. Delivery models must shift from project-centric implementations toward
1053 capability stewardship, where architectural elements are owned, governed, and evolved over time.

1054 Rather than acting as control gates that slow delivery or solution factories that fragment ownership,
1055 Centers of Excellence are most effective when positioned as enablers of architectural coherence,
1056 shared standards, and lifecycle learning across the organization (ISPE, 2019).

1057 7.5. FAILURE MODES WHEN PEOPLE ARE NOT ALIGNED

1058 When organizational roles and skills are not aligned with the digital architecture, predictable
1059 failure modes emerge:

- 1060 • Architectural pathways are bypassed through manual workarounds
- 1061 • Semantic drift is reintroduced via spreadsheets and local tools
- 1062 • Batch review effort increases rather than decreases
- 1063 • Advanced analytics and AI outputs are distrusted or ignored

1064 In these cases, the architecture may exist technically but not operationally. Fragmentation
1065 reappears not because the technology failed, but because people were not positioned to operate
1066 within it. Industry maturity assessments consistently confirm this pattern: BioPhorum’s digital
1067 transformation work (BioPhorum, 2023) identifies organizational readiness as a primary
1068 differentiator between organizations that scale digital value and those that remain in pilot cycles.

1069

1070 Architecture without people alignment recreates the same fragmentation it seeks to eliminate.

1071

Key Takeaway

Treating people as semantic and decision-making components of the architecture is essential to achieving scalable technology transfer, continuous batch disposition, and credible adoption of advanced analytics and AI.

1072 8. BATCH DISPOSITION AS AN ARCHITECTURAL OUTCOME

1073 Batch disposition has historically been treated as a discrete quality activity performed at the
1074 conclusion of manufacturing execution. In this model, data is gathered from multiple systems,
1075 contextual gaps are resolved through manual review, and quality decisions are made
1076 retrospectively based on the completeness of records rather than the continuous assessment of
1077 execution against intent. While effective in regulated environments, this approach places a
1078 significant operational burden on quality organizations and becomes increasingly fragile as
1079 manufacturing complexity, product portfolios, and network scale grow. The FDA’s process
1080 validation guidance (FDA, 2011) establishes a lifecycle approach encompassing Stage 1 (Process
1081 Design), Stage 2 (Process Qualification), and Stage 3 (Continued Process Verification)—yet the
1082 episodic disposition model is fundamentally misaligned with Stage 3’s expectation of ongoing, data-
1083 driven process assurance.

1084 This paper advances a different perspective: batch disposition is not a workflow to be optimized,
1085 but an outcome that emerges from architectural design choices. When manufacturing intent,
1086 execution events, and quality evidence are preserved coherently across the lifecycle, disposition
1087 shifts from an episodic activity to a continuous, evidence-driven capability. Figure 5 contrasts the

1088 traditional retrospective disposition model with the continuous, evidence-driven approach enabled
1089 by the IDDC.

1090 8.1. LIMITATIONS OF EPISODIC, RETROSPECTIVE DISPOSITION

1091 Traditional batch disposition relies on reconstructing execution context after manufacturing has
1092 concluded. Evidence is assembled from disparate systems, often with inconsistent semantics and
1093 incomplete temporal alignment. Reviewers must infer intent, reconcile discrepancies, and apply
1094 expert judgment to determine whether a batch meets release criteria. ICH Q10 (ICH, 2008)
1095 envisions batch release as an outcome of effective pharmaceutical quality systems with embedded
1096 knowledge management—an aspiration that episodic, reconstruction-dependent disposition
1097 cannot fulfill at scale.

1098 As articulated in BioPhorum’s Digital Batch Disposition Manifesto (BioPhorum, 2023), this
1099 retrospective model scales poorly. Manual reconciliation increases with product complexity, while
1100 review timelines lengthen and variability in interpretation grows. Even in highly digitalized
1101 environments, the absence of architectural continuity forces quality decisions to depend on human
1102 reconstruction of meaning rather than on inherently trustworthy evidence.

1103 These limitations are not primarily procedural. They reflect architectures that were never designed
1104 to support continuous disposition. Evidence is generated, but not structured; data is available, but
1105 not contextualized; intent exists, but is not explicitly bound to execution.

1106 8.2. CONTINUOUS DISPOSITION ENABLED BY ARCHITECTURE

1107 An intent-driven architecture fundamentally alters how disposition evidence is created and
1108 evaluated. When execution is captured as contextualized events and bound to the manufacturing
1109 intent in effect at the time, evidence is accumulated progressively, not assembled after the fact. This
1110 architectural approach operationalizes Stage 3 continued process verification (FDA, 2011) as a
1111 design property rather than a procedural aspiration.

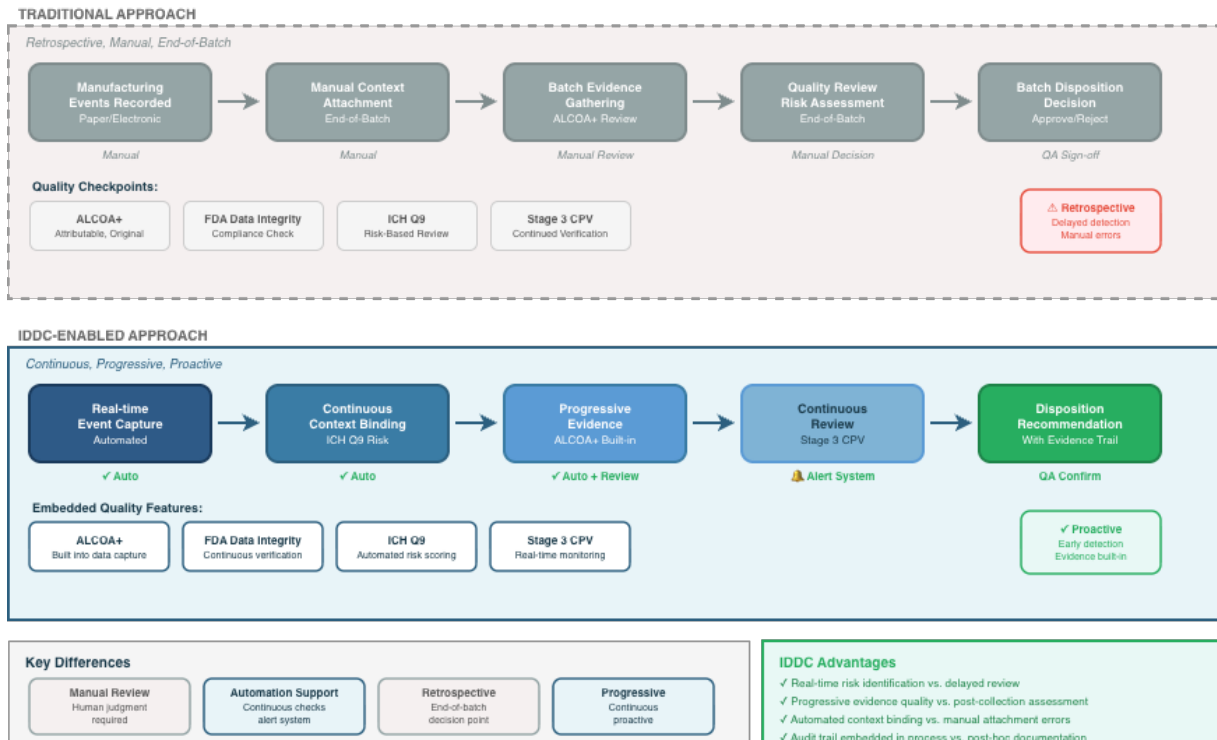

1112 In this model, each execution event contributes incrementally to the disposition decision.
1113 Deviations, excursions, and anomalies are evaluated in context, as they occur, rather than being
1114 rediscovered during final review. Quality oversight shifts from exhaustive record assembly toward
1115 focused assessment of uncertainty and risk.

1116 The IDDC enables this transition by preserving the semantic relationships between process intent,
1117 execution reality, and quality expectations. Evidence generated within this core retains provenance,
1118 lineage, and temporal coherence by design, allowing quality decisions to be informed continuously
1119 throughout the batch lifecycle. This directly supports ICH Q10’s emphasis on knowledge
1120 management as a lifecycle enabler of product quality (ICH, 2008) and aligns with ICH Q8(R2)’s
1121 vision of control strategies that are understood well enough to be monitored continuously (ICH,
1122 2009).

1123 This architectural approach aligns directly with the principles articulated in the Digital Batch
1124 Disposition Manifesto, which emphasizes that digitalization alone does not yield faster or more
1125 reliable disposition unless evidence is contextualized and trustworthy at the point of generation.

Continuous Batch Disposition

From Events to Evidence to Decision

1126

1127

1128

Figure 5. Continuous Batch Disposition: From Events to Evidence to Decision. The IDDC enables progressive evidence accumulation replacing retrospective reconstruction.

1129

1130

1131

1132

1133

1134

1135

1136

1137

Figure 5 illustrates how the IDDC transforms batch disposition from an episodic, retrospective activity into a continuous, proactive capability. In the traditional approach (top), evidence is assembled after manufacturing concludes, requiring manual reconciliation across systems and retrospective context reconstruction. In the IDDC-enabled approach (bottom), manufacturing events are bound to context at the point of execution, evidence accumulates progressively throughout the batch, and quality review shifts from data assembly to exception-focused assessment. This architectural shift enables real-time visibility into batch status, earlier detection of deviations, and disposition decisions that are faster, more consistent, and more defensible—without sacrificing the rigor required for regulatory compliance.

1138

8.3. EVIDENCE AS A LIFECYCLE ASSET

1139

1140

1141

1142

1143

1144

Reframing batch disposition as an architectural outcome requires a corresponding reframing of evidence. Evidence must be treated as a lifecycle asset, generated during execution, enriched with context, and preserved for downstream review, learning, and regulatory engagement. The ALCOA+ principles (FDA, 2018) define the attributes that make evidence trustworthy—attributable, legible, contemporaneous, original, and accurate—each of which is more reliably achieved when evidence is accumulated architecturally rather than assembled retrospectively.

1145

1146

1147

1148

When evidence is accumulated continuously, disposition becomes less about verifying record completeness and more about confirming conformance to intent. This distinction is critical. Completeness can be achieved through manual effort; conformance requires architectural alignment.

1149

1150

This approach also enables earlier detection of quality risk. Trends, patterns, and deviations can be assessed against intent while operators are engaged to provide context and corrective action

1151 remains possible, reducing reliance on post hoc justification and minimizing downstream
1152 disruption.

1153 8.4. IMPLICATIONS FOR QUALITY ORGANIZATIONS

1154 The organizational implications of continuous disposition align with the socio-technical model
1155 developed in Section 7: as the architecture assumes responsibility for evidence accumulation,
1156 quality professionals redirect their expertise from information assembly to risk evaluation and
1157 informed judgment — a transition that strengthens both operational efficiency and regulatory
1158 confidence.

1159 This shift is consistent with the socio-technical model described in Section 7. As evidence quality
1160 improves, trust in digital records increases, and the credibility of review by exception and other
1161 advanced quality models improves accordingly. Importantly, this transition does not require
1162 regulatory reinterpretation; it requires architectural readiness. ICH Q12’s framework for managing
1163 established conditions and post-approval changes (ICH, 2019) provides the regulatory foundation
1164 for this evolution: when evidence structures are architecturally governed, the distinction between
1165 established conditions and operational parameters becomes tractable rather than ambiguous.

1166 8.5. DISPOSITION AS PROOF OF ARCHITECTURAL MATURITY

1167 Batch disposition is one of the most stringent tests of digital manufacturing architecture. Unlike
1168 analytics or visualization, disposition decisions carry direct regulatory and patient impact. If an
1169 architecture can support timely, confident, and consistent disposition across products and sites, it
1170 demonstrates that intent, context, and evidence are truly preserved across the lifecycle. ICH Q9(R1)
1171 (ICH, 2023) reinforces that quality risk management must be systematic, science-based, and
1172 embedded in the quality system—characteristics that are achievable only when the underlying
1173 architecture provides structured, trustworthy evidence for risk assessment.

1174 In this sense, batch disposition functions as a leading indicator of architectural maturity.
1175 Architectures that rely on manual reconciliation will struggle to scale disposition, regardless of
1176 digital tooling. Architectures that preserve meaning by design enable disposition to compound in

Key Takeaway

Batch disposition is not accelerated by digitizing quality workflows, but by architecting for continuous evidence generation and intent preservation. When disposition is treated as an architectural outcome rather than a downstream activity, quality decisions become faster, more consistent, and more scalable without sacrificing regulatory rigor.

1177 efficiency, reliability, and trust as complexity increases.

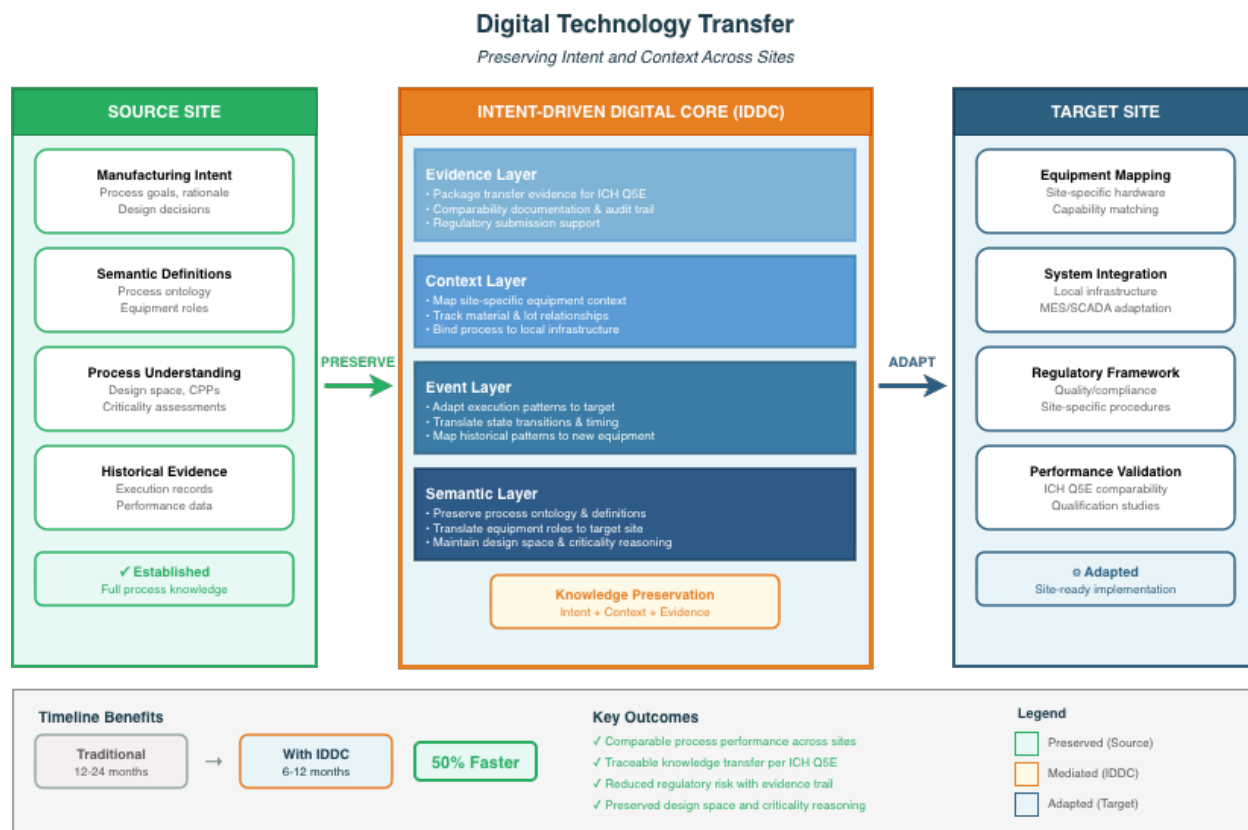

1178

1179 9. DIGITAL TECHNOLOGY TRANSFER AS THE ULTIMATE STRESS TEST

1180 Technology transfer is one of the most revealing and least forgiving phases of the manufacturing
1181 lifecycle. It requires that scientific understanding, process intent, execution models, and quality
1182 expectations remain interpretable as they move across organizational, geographic, and technical
1183 boundaries. Unlike steady-state manufacturing, technology transfer exposes whether continuity has
1184 been architected or merely assumed.

1185 For this reason, digital technology transfer functions as the ultimate stress test of a digital
1186 architecture. Architectures that appear sufficient within a single site or system landscape often fail

1187 under the pressure of transfer, where implicit assumptions, local interpretations, and fragmented
1188 representations are forced into the open.

1189 Figure 6. Digital Technology Transfer: Preserving Intent and Context Across Sites. The IDDC is projected to enable significant reduction in
1190 transfer timelines while maintaining traceable comparability aligned with ICH Q5E requirements.
1191

1192 As Figure 6 demonstrates, the IDDC proposes a fundamentally different approach to technology
1193 transfer. Industry guidance consistently documents that traditional transfer processes require 12–
1194 24 months for complex biologics transfers, with some extending beyond 24 months depending on
1195 process complexity and receiving site readiness (ISPE, 2018; PDA, 2022; WHO, 2022). Rather than
1196 translating process knowledge through documentation that must be reinterpreted at the receiving
1197 site, the architecture preserves manufacturing intent in a portable, semantically consistent form.
1198 The source site’s process definitions, control strategies, and execution patterns are captured within
1199 the IDDC’s four layers; during transfer, these representations are instantiated at the target site
1200 while adapting to local equipment and system configurations. This approach is projected to reduce
1201 transfer timelines significantly by eliminating the manual reconstruction of process understanding
1202 that WHO TRS 1044 identifies as a primary source of transfer delays (WHO, 2022). Critically, it
1203 supports ICH Q5E comparability demonstration through structured, traceable data rather than
1204 reconstructed documentation (ICH, 2004), enabling immediate comparability of execution evidence
1205 between sending and receiving sites.

1206 9.1. WHY TECHNOLOGY TRANSFER EXPOSES ARCHITECTURAL FRAGILITY

1207 Technology transfer amplifies complexity along multiple dimensions simultaneously. Processes
1208 move from development to manufacturing, from one site to another, or from internal operations to
1209 external partners. Equipment, automation platforms, and execution systems change, while
1210 regulatory expectations for demonstrated comparability remain constant (ICH, 2004; FDA, 2011).

1211 Under these conditions, any ambiguity in how manufacturing intent is represented becomes a
1212 source of delay, rework, or risk.

1213 Historically, organizations have compensated for this fragility through extensive documentation,
1214 expert oversight, and extended stabilization periods. While often effective, these approaches scale
1215 poorly (ISPE, 2018; WHO, 2022). As product portfolios expand and manufacturing networks
1216 become more distributed, reliance on manual interpretation and tacit knowledge becomes a
1217 structural constraint that industry guidance increasingly recognizes as a barrier to effective
1218 transfer (PDA, 2022).

1219 Many technology transfer challenges attributed to “process complexity” or “site readiness” are in
1220 fact architectural in nature. When intent is embedded implicitly in documents, spreadsheets, or
1221 system configurations, it must be reconstructed at each receiving site. This reconstruction
1222 introduces variability and undermines repeatability, regardless of the maturity of individual
1223 systems. ICH Q10 recognizes that effective knowledge management across the product lifecycle is
1224 essential for maintaining process understanding during transfer (ICH, 2008), while ICH Q12
1225 provides the regulatory framework for managing post-approval changes that transfers often
1226 necessitate (ICH, 2019). Figure 6 illustrates how an intent-driven architecture enables digital
1227 technology transfer by preserving meaning across site boundaries.

1228 9.2. INTENT PORTABILITY AS THE CORE REQUIREMENT

1229 Digital technology transfer succeeds only when manufacturing intent is portable. Portability does
1230 not imply uniform execution; sites will always differ in equipment, automation, and operational
1231 practices. Rather, it requires that the meaning of the process—its objectives, constraints, and
1232 quality expectations—remain consistent even as execution models vary. This is the operational
1233 expression of what ICH Q5E terms comparability: demonstrating that a product’s quality attributes
1234 are not adversely affected by changes in the manufacturing process, including site transfers (ICH,
1235 2004).

1236 An intent-driven architecture enables this portability by decoupling intent from any single system
1237 or site implementation. When intent is preserved within the architectural core, receiving sites do
1238 not reinterpret the process; they instantiate it. Local adaptation becomes a bounded exercise,
1239 governed by explicit constraints rather than implicit assumptions.

1240 This distinction is critical. Translation implies reinterpretation; instantiation implies fidelity.
1241 Architectures that support instantiation by design reduce transfer timelines, improve comparability
1242 of outcomes, and lower dependence on extended expert involvement. WHO TRS 1044 emphasizes
1243 that the completeness and accuracy of transferred process knowledge directly determines transfer
1244 outcomes (WHO, 2022); an intent-driven architecture addresses this by making that knowledge
1245 structurally complete rather than documentarily complete.

1246 The mechanism through which intent portability is achieved is the ontology access architecture
1247 described in this paper’s treatment of ontology as architectural infrastructure. When manufacturing
1248 intent is encoded against a governed ontology and systems access that ontology programmatically
1249 —rather than through manual transcription into local configurations—the receiving site
1250 instantiates the same semantic structure. Process definitions, material specifications, and control
1251 strategy parameters retain their governed meaning because both sites resolve them against the
1252 same ontological source. This is the architectural equivalent of what ICH Q8(R2) envisions as a
1253 design space that is understood well enough to be transferred rather than re-derived (ICH, 2009).
1254 The ontology does not eliminate local adaptation—equipment differences, facility constraints, and
1255 operational practices will always require site-specific configuration—but it constrains adaptation

1256 to occur within a semantically governed boundary, ensuring that comparability is preserved by
1257 design rather than reconstructed through post-transfer analysis.

1258 9.3. DIGITAL TRANSFER BEYOND DOCUMENTATION

1259 Traditional digital technology transfer efforts often focus on digitizing transfer artifacts: electronic
1260 process descriptions, general/master recipes, structured batch records, or standardized parameter
1261 lists. While necessary, these artifacts do not guarantee continuity of meaning. As WHO TRS 1044
1262 notes, the transfer of documented knowledge without its underlying context and rationale is a
1263 recurring source of transfer failures across the industry (WHO, 2022).

1264 Effective digital transfer requires that execution context and evidence generated at the receiving
1265 site can be evaluated against the same intent and quality expectations defined upstream. This
1266 demands semantic consistency, event coherence, and contextual binding across environments—
1267 capabilities that ISPE’s technology transfer guidance identifies as critical success factors for modern
1268 transfer programs (ISPE, 2018).

1269 When these conditions are met, early manufacturing runs at a new site generate evidence that is
1270 immediately comparable to development and prior production experience. Deviations can be
1271 assessed meaningfully, and stabilization efforts can focus on true process differences rather than
1272 representational mismatches.

1273 9.4. TRANSFER ACROSS NETWORKS AND PARTNERS

1274 The architectural demands of technology transfer increase further in extended manufacturing
1275 networks. Contract development and manufacturing organizations (CDMOs) now execute a
1276 significant and growing share of biopharmaceutical production, yet transfer to and between CDMOs
1277 remains among the most failure-prone activities in the industry (PDA, 2022). The challenges are
1278 both technical and organizational: CDMOs operate their own automation platforms, quality
1279 systems, and data architectures, while sponsors retain regulatory responsibility for product quality.
1280 Without a shared architectural foundation, transfer relies heavily on contractual artifacts,
1281 technology transfer packages assembled as static document sets, and extensive manual oversight—
1282 a model that WHO TRS 1044 explicitly identifies as insufficient for complex products (WHO, 2022).

1283 An intent-driven digital architecture provides a mechanism to maintain continuity without
1284 imposing uniform systems or tools across partners. By externalizing manufacturing intent and
1285 preserving it in a semantically governed, system-agnostic form, sponsors and CDMOs can achieve
1286 interoperability while respecting local execution environments (as illustrated in Figure 6). The
1287 IDDC’s ontology access architecture is particularly relevant here: rather than requiring CDMOs to
1288 adopt the sponsor’s system landscape, the architecture requires only that both parties resolve
1289 process definitions against a shared ontological source. This approach aligns with the ISPE
1290 technology transfer guidance’s emphasis on transfer protocols that separate process understanding
1291 from platform-specific implementation (ISPE, 2018), and with ICH Q10’s vision of quality system
1292 interoperability across organizational boundaries (ICH, 2008).

1293 This capability is increasingly important as manufacturing strategies emphasize flexibility,
1294 resilience, and networked production models. The trend toward platform manufacturing, multi-
1295 product facilities, and rapid deployment of new modalities—particularly cell and gene therapies
1296 with patient-specific requirements—amplifies the need for architecturally portable intent.
1297 Organizations that achieve this portability will be positioned to treat manufacturing network design
1298 as a strategic capability rather than a logistical constraint.

1299 **9.5. TECHNOLOGY TRANSFER AS ARCHITECTURAL VALIDATION**

1300 Technology transfer provides a clear, outcome-based measure of architectural maturity.
1301 Architectures that preserve intent, context, and evidence by design enable transfer to compound in
1302 efficiency and reliability as experience grows. Architectures that rely on manual reconciliation reset
1303 transfer effort with each new site or product—a pattern that current industry guidance consistently
1304 identifies as unsustainable at the scale and speed modern manufacturing networks demand (ISPE,
1305 2018; WHO, 2022; PDA, 2022).

1306 In this sense, technology transfer is not merely an operational milestone; it is a validation of
1307 whether digital architecture truly supports lifecycle continuity. If intent can be transferred digitally
1308 without reinterpretation, the architecture is sound. If not, no amount of tooling or documentation
1309 will fully compensate.

Key Takeaway

Digital technology transfer does not fail because manufacturing systems differ; it fails when manufacturing intent is not portable. Architectures that preserve meaning, context, and evidence across the lifecycle transform technology transfer from a high-risk translation exercise into a repeatable instantiation process, enabling scale, resilience, and confidence in increasingly complex manufacturing networks.

1310

1311 **10. AI ENABLEMENT AS A CONSEQUENCE OF ARCHITECTURE**

1312 Artificial intelligence is increasingly positioned as the next step in life sciences digital
1313 transformation. In practice, however, many AI initiatives stall at prototype stages or fail to
1314 transition into reliable, regulated operations. The primary reason is rarely algorithmic
1315 sophistication. Rather, it is the absence of a lifecycle-ready architectural foundation that preserves
1316 meaning, context, and evidence with sufficient integrity for models to be trusted, validated, and
1317 sustained over time. Sculley et al. (2015) demonstrate that machine learning systems accumulate
1318 “hidden technical debt” through unstable data dependencies, feedback loops, and configuration
1319 complexity—debt that compounds rapidly when deployed on architecturally fragmented
1320 manufacturing data.

1321 This paper therefore treats AI enablement not as a driver for architecture, but as a consequence of
1322 it. AI systems consume manufacturing reality. If manufacturing reality is fragmented, semantically
1323 inconsistent, or poorly evidenced, AI inherits those weaknesses, regardless of model performance
1324 in controlled settings. Conversely, when manufacturing intent, execution events, and quality-
1325 relevant evidence are preserved coherently across the lifecycle, AI becomes more feasible, more
1326 scalable, and more credible in regulated environments.

1327 **10.1. WHY AI FAILS TO SCALE IN REGULATED MANUFACTURING**

1328 Across the industry, AI proofs of concept frequently succeed in local contexts, then fail to scale
1329 across sites, products, or time. Several structural causes recur:

- 1330 • Context collapse: model features are available, but their meaning varies across systems,
1331 sites, or lifecycle phases
- 1332 • Unverifiable provenance: training and inference data cannot be traced to authoritative
1333 sources or aligned to the conditions under which it was generated

- 1334 • Semantic drift: the same process concept is represented differently across stages,
1335 undermining model stability and reproducibility
- 1336 • Temporal incoherence: event sequences and state transitions cannot be reconstructed
1337 reliably, weakening causal inference and operational interpretability
- 1338 • Credibility gaps: models lack a robust, risk-based justification aligned to a defined context of
1339 use, limiting regulatory and business acceptance

1340 Regulators and industry groups have increasingly converged on the idea that credibility depends on
1341 defining and bounding context of use, establishing traceable data foundations, and maintaining
1342 lifecycle controls on models and their inputs. The FDA’s guidance on AI and machine learning in
1343 drug and biological product development (FDA, 2023) explicitly frames AI credibility as risk-based
1344 and context-dependent, emphasizing the need to justify data relevance and model performance for
1345 the intended use.

1346 Similarly, the NIST AI Risk Management Framework (NIST, 2023) emphasizes lifecycle processes,
1347 test and evaluation, and governance to manage AI risk, reflecting the broader industry realization
1348 that AI is not a one-time build, but a continuously managed capability.

1349 10.2. INTENT-DRIVEN DIGITAL CORE AS THE ENABLER OF AI READINESS

1350 The architectural mechanism that makes AI scalable in this paper’s model is the IDDC. By
1351 preserving manufacturing intent, semantic meaning, event fidelity, contextual binding, and quality
1352 evidence independently of any single system implementation, the IDDC creates the conditions
1353 under which AI can be trained and deployed with confidence (see Figure 2).

1354 This is a critical distinction from conventional “AI-ready data platform” narratives. Data platforms
1355 can centralize storage and compute, but they do not inherently preserve meaning. AI enablement
1356 requires not only data access, but interpretability, traceability, and comparability across the
1357 lifecycle.

1358 In practical terms, the IDDC supports AI readiness by ensuring that:

- 1359 • Intent is explicit and versioned, grounded in the ontology landscape shown in Figure 4,
1360 enabling models to learn against authoritative definitions rather than emergent proxies
- 1361 • Execution is represented as coherent events, supporting temporal reasoning and reducing
1362 ambiguity in state-dependent behaviors
- 1363 • Context is bound at generation, minimizing downstream inference and increasing feature
1364 reliability
- 1365 • Evidence is structured for review, enabling GxP-aligned confidence in model inputs and
1366 outputs
- 1367 • This framing is consistent with the BioPhorum consortium’s data characteristics framework
1368 (BioPhorum, 2026), which organizes AI-ready data requirements into four groups — data
1369 observability, data quality, data availability, and machine understandability — and
1370 demonstrates that the characteristics most critical for AI vary by use case archetype rather
1371 than being universally applicable. The framework is discussed in detail in the following
1372 subsections.

1373 10.3. AI-READY DATA AS LIFECYCLE EVIDENCE, NOT JUST “CLEAN DATA”

- 1374 • A common simplification is to equate AI readiness with data quality improvements, such as
1375 completeness, accuracy, and standardization. The FAIR principles (Wilkinson et al., 2016)—
1376 findable, accessible, interoperable, and reusable—represent an important advance, but
1377 even FAIR compliance is insufficient for manufacturing AI: data may be findable and

1378 accessible yet lack the contextual binding and semantic consistency that regulated decision-
1379 making demands.

- 1380 • AI readiness can be distinguished as a multi-factor condition involving:
 - 1381 • data observability (understanding condition, drift, and failure modes)
 - 1382 • metadata versus context (what describes data versus what makes it interpretable)
 - 1383 • lineage and provenance (traceability across transformation and augmentation)
 - 1384 • semantic consistency (stable meaning across systems and phases)
 - 1385 • change dynamics (concept drift, process drift, and evolving intent)
- 1386 • These distinctions align tightly with what regulators and risk frameworks expect: AI
1387 outputs must be interpreted within their context of use and supported by defensible
1388 evidence about data fitness, model performance, and lifecycle controls. The EU AI Act
1389 (European Union, 2024) classifies AI systems by risk level and imposes stringent
1390 requirements on high-risk applications—a category that encompasses many manufacturing
1391 quality and safety decisions. ISO/IEC 42001 (ISO/IEC, 2023) further requires organizations
1392 to establish AI management systems with explicit governance of data quality, model
1393 lifecycle, and risk assessment.
- 1394 • Within this paper’s intent-driven architecture, AI-ready data is best understood as lifecycle
1395 evidence that is fit to support a specified analytical purpose. Evidence is not defined by
1396 volume or resolution, but by interpretability and traceability. High-resolution time-series
1397 signals remain essential for control and troubleshooting at the point of generation, but AI
1398 systems operating across lifecycle phases typically require event-centric abstractions and
1399 contextual coherence rather than raw signal persistence. This mirrors the architectural
1400 rationale established in Section 6.

1401 10.4. CROSS-INDUSTRY VALIDATION: THE BIOPHORUM DATA CHARACTERISTICS 1402 FRAMEWORK

- 1403 • The preceding distinction between AI readiness and data quality finds direct validation in
1404 the BioPhorum consortium’s work on managing structured and unstructured data for AI
1405 (BioPhorum, 2026). Developed by a cross-company working group representing major
1406 biopharmaceutical manufacturers, the BioPhorum framework establishes that AI-ready
1407 data must satisfy characteristics organized into four groups, each answering a distinct
1408 question about the data’s fitness for AI consumption.
- 1409 • **Data observability** addresses what can be assessed without domain knowledge —
1410 completeness, consistency, timeliness, schema conformance, integrity, lineage, and
1411 precision. These are characteristics that data engineering teams can measure and monitor
1412 programmatically, providing the baseline assurance that data pipelines are functioning
1413 correctly.
- 1414 • **Data quality** addresses what requires process expertise to evaluate — validity,
1415 reasonability, credibility, relevance, representativeness, and authoritativeness. These
1416 characteristics depend on understanding how data was generated and what constitutes
1417 expected behavior in a specific manufacturing context. They cannot be assessed by schema
1418 validation alone.
- 1419 • **Data availability** addresses what enables AI systems to access data appropriately —
1420 findability, accessibility, interoperability, reusability, confidentiality, scalability, and speed
1421 of retrieval. These are infrastructure and governance characteristics that determine

1422 whether technically sound, quality-assured data can actually reach the AI systems that need
1423 it.

1424 • **Machine understandability** addresses what enables AI systems to interpret data
1425 appropriately — contextualization, semantic connection, and clarity. The BioPhorum
1426 framework identifies this as the group that represents a genuinely new challenge beyond
1427 traditional data management, noting that optimal machine understandability requires
1428 alignment between the data’s inbuilt characteristics and the organization’s ontology,
1429 knowledge graph, and process documentation.

1430 • This four-group framework maps directly to the IDDC’s layered architecture. Data
1431 observability and data quality are primarily served by the Event and Evidence layers — the
1432 architectural commitment to capturing execution data with temporal integrity, contextual
1433 binding, and traceable provenance. Data availability is served by the integration and data
1434 platform layers — the infrastructure that makes semantically grounded data findable,
1435 accessible, and interoperable across systems and sites. Machine understandability is served
1436 by the Semantic Layer — the ontological foundation that provides AI systems with the
1437 structured meaning required to interpret data beyond isolated values.

1438 • The BioPhorum framework further validates a central argument of this paper: AI readiness
1439 is not a binary state but a context-dependent assessment. The framework demonstrates
1440 that the data characteristics most critical for AI vary by use case archetype. Knowledge and
1441 sense-making applications prioritize semantic connection. Classification and detection
1442 applications require integrity, precision, and contextual binding. Prediction and forecasting
1443 demand temporal completeness and schema conformance. Decision support requires
1444 auditability and legal compliance. This archetype-to-characteristics mapping provides an
1445 empirically grounded method for determining which architectural capabilities must be
1446 most mature for a given AI deployment — directly operationalizing the “context of use”
1447 principle discussed in the following subsection.

1448 • The convergence between the BioPhorum framework and the IDDC architecture is not
1449 coincidental. Both emerge from the same underlying recognition: that AI in regulated
1450 manufacturing fails not because models are inadequate, but because the data they consume
1451 lacks the semantic consistency, contextual integrity, and traceable provenance that
1452 regulated environments demand. The BioPhorum work validates this at the consortium
1453 level, across organizations representing the majority of global biopharmaceutical
1454 production.

1455 10.5. FROM USE CASE TO CONTEXT OF USE

1456 • AI initiatives fail when use cases are articulated as “apply AI to X” rather than as defined
1457 contexts of use that specify:

- 1458 • the decision or action the model will inform
- 1459 • the risk associated with incorrect outputs
- 1460 • the operational environment in which the model will be used
- 1461 • the acceptable uncertainty and performance bounds
- 1462 • the evidence required for trust, review, and validation

1463 • This aligns closely with the FDA’s credibility framework (FDA, 2023), which emphasizes
1464 defining context of use and establishing credibility proportionate to risk, and with the NIST
1465 AI RMF’s (NIST, 2023) emphasis on mapping context, measuring performance, and
1466 governing lifecycle risks.

- 1467 • In regulated manufacturing, the implication is direct: AI should be positioned first as a
1468 decision-support capability with bounded scope, not as an autonomous controller. Industry
1469 frameworks such as ISPE’s guidance on AI in pharmaceutical manufacturing (ISPE, 2025)
1470 underscore that without lifecycle assurance and validation thinking from the outset, AI
1471 programs tend to remain trapped in pilot cycles.

1472 10.6. ARCHITECTURAL PREREQUISITES FOR AI ACROSS THE LIFECYCLE

- 1473 • While AI use cases vary, the architectural prerequisites tend to converge. In the context of
1474 this paper’s architecture, scalable AI requires the following prerequisites to be satisfied as
1475 lifecycle properties, not project deliverables:

1476 10.6.1. SEMANTIC STABILITY

- 1477 • Models require stable meaning. If “batch start,” “mixing phase,” “hold time,” or “CPP
1478 excursion” are defined differently across systems or sites, model training becomes a
1479 function of representational artifacts rather than manufacturing reality.
- 1480 • The ontology construct introduced in Section 5 addresses this by externalizing meaning as a
1481 governed contract, enabling semantic interoperability across discovery, development, and
1482 manufacturing.

1483 10.6.2. EVENT COHERENCE AND TEMPORAL INTEGRITY

- 1484 • Many manufacturing AI use cases are fundamentally temporal: they depend on the ordering
1485 of events, state transitions, and time-in-state. Without event coherence, models cannot
1486 reliably distinguish causal signals from correlated noise.
- 1487 • Event-centric execution representation (Section 6) provides this temporal backbone,
1488 allowing inference to be anchored in execution reality rather than inferred timestamps.

1489 10.6.3. CONTEXT BINDING AND FEATURE RELIABILITY

- 1490 • In manufacturing, a measurement is rarely meaningful without context. A temperature
1491 reading, pressure signal, or assay result becomes relevant only when tied to the correct
1492 step, material state, equipment role, and control strategy.
- 1493 • Binding context at generation reduces feature instability and improves model portability
1494 across lifecycle phases and sites.

1495 10.6.4. PROVENANCE, LINEAGE, AND TRANSFORMATION TRANSPARENCY

- 1496 • AI systems are sensitive to data transformations, augmentations, and label construction. If
1497 these transformations are not traceable, model training becomes irreproducible, and
1498 inference becomes difficult to defend.
- 1499 • The NIST AI RMF (NIST, 2023) and ISO/IEC 42001 (ISO/IEC, 2023) both emphasize the
1500 importance of data provenance and transformation integrity for trustworthy AI, while
1501 GAMP 5 (ISPE, 2022) provides the GxP-specific framework for validating the computerized
1502 systems that manage these transformations.

1503 10.6.5. EVIDENCE MODELS FOR GXP CREDIBILITY

- 1504 • In regulated contexts, models must be validated and maintained. ISPE’s AI in
1505 pharmaceutical manufacturing guidance (ISPE, 2025) emphasizes that assurance of
1506 integrity and quality of outputs is essential and must be considered early to avoid pilot
1507 stagnation. Rudin (2019) argues more broadly that high-stakes domains should prioritize

1508 inherently interpretable models over post-hoc explanations of black boxes—a position with
1509 direct implications for GxP contexts where decision rationale must be auditable.

- 1510 • This paper’s evidence layer concept supports that requirement by structuring data and
1511 context so it remains suitable for review and compliance consumption.

1512 10.7. AI ENABLEMENT ACROSS KEY MANUFACTURING DOMAINS

- 1513 • To illustrate how these prerequisites manifest, AI enablement can be grouped into several
1514 archetypal domains. The purpose here is not to enumerate use cases exhaustively, but to
1515 show how architecture determines feasibility.

1516 10.7.1. PROCESS MONITORING AND ANOMALY DETECTION

- 1517 • These applications benefit from high-resolution signals locally but require event and
1518 context coherence to scale beyond single-unit deployments. Without contextual binding,
1519 anomaly outputs are difficult to interpret and operationalize.

1520 10.7.2. PREDICTIVE QUALITY AND DEVIATION RISK FORECASTING

- 1521 • These models require strong semantic stability and evidence traceability because they
1522 inform quality decisions and may be subject to heightened scrutiny. Inconsistent definitions
1523 of quality attributes or process states undermine credibility.

1524 10.7.3. TECH TRANSFER LEARNING AND CROSS-SITE GENERALIZATION

- 1525 • Cross-site learning is a direct beneficiary of the IDDC. If execution events and context are
1526 comparable, models can generalize and support transfer readiness. If not, each site becomes
1527 an isolated training domain and AI value cannot compound.
- 1528 • This mirrors Section 9’s argument that tech transfer is a stress test of architecture; it is also
1529 a stress test of AI generalizability.

1530 10.7.4. KNOWLEDGE RETRIEVAL AND DECISION SUPPORT

- 1531 • Generative AI, retrieval-augmented generation, and agentic patterns are increasingly
1532 discussed across the industry, including within BioPhorum programming.
- 1533 • However, these approaches are only as reliable as the semantic organization of the
1534 underlying knowledge. Without controlled meaning, provenance, and evidence structures,
1535 generative outputs become difficult to trust in regulated decisions.
- 1536 • The BioPhorum data characteristics framework (BioPhorum, 2026) reinforces this point:
1537 knowledge retrieval and decision support applications require the highest levels of
1538 semantic connection and contextualization — precisely the machine understandability
1539 characteristics that depend on ontological grounding. Without the Semantic Layer that
1540 ontology provides, generative and agentic AI outputs in regulated contexts cannot achieve
1541 the interpretability and traceability that quality organizations require for trust.

1542 10.8. FAILURE MODES WHEN AI IS PURSUED WITHOUT ARCHITECTURAL READINESS

- 1543 • A key risk in life sciences digital strategies is the inversion of sequencing: pursuing AI
1544 before establishing the foundations that make it trustworthy and scalable. When this
1545 occurs, predictable failure modes follow:
- 1546 • Models become dependent on local feature engineering and informal context knowledge
- 1547 • Outputs are not reproducible across time, sites, or lifecycle phase

- 1548 • Validation becomes difficult because inputs and transformations cannot be defended
- 1549 • Quality organizations distrust results due to weak evidence lineage
- 1550 • Programs remain trapped in pilots, reinforcing skepticism about AI value
- 1551 • These are not primarily model failures. They are architectural failures.

1552 10.9. IMPLICATIONS FOR PROGRAM DESIGN AND GOVERNANCE

- 1553 • AI enablement requires a governance model that matches its lifecycle nature. Regulatory
1554 and standards bodies increasingly emphasize that AI must be governed through continuous
1555 risk management, credibility assessment, and lifecycle controls. The NIST AI RMF (NIST,
1556 2023), ISO/IEC 42001 (ISO/IEC, 2023), and the EU AI Act (European Union, 2024) converge
1557 on a common expectation: AI governance must be risk-proportionate, lifecycle-aware, and
1558 embedded in organizational management systems rather than treated as a one-time
1559 validation exercise.
- 1560 • Within the framing of this paper, governance should focus on:
 - 1561 • defining and approving contexts of use
 - 1562 • ensuring data readiness is measurable and observable, not assumed
 - 1563 • treating semantic constructs and evidence models as controlled lifecycle assets
 - 1564 • embedding accountability for model operation, monitoring, and change management
 - 1565 • maintaining transparency on drift, retraining triggers, and performance boundaries
- 1566 • This aligns with ISPE’s governance and QA framing for AI in GxP contexts (ISPE, 2025),
1567 which emphasizes sustained assurance rather than one-time validation events. This paper
1568 will provide a more detailed discussion of Governance in Section 12.

1569 10.10. FUTURE DIRECTIONS: FROM DECISION SUPPORT TO AGENTIC 1570 MANUFACTURING INTELLIGENCE

- 1571 • The preceding subsections establish that AI enablement in regulated manufacturing is
1572 fundamentally an architectural capability, not a technology deployment. The BioPhorum
1573 data characteristics framework validates that AI-ready data requires semantic consistency,
1574 contextual binding, and traceable provenance — capabilities that the IDDC provides by
1575 design. The failure modes described above demonstrate what happens when AI is pursued
1576 without these foundations. This subsection looks forward to a frontier that current
1577 architectural investments make possible: the emergence of agentic AI systems that can
1578 perceive, reason about, and act within manufacturing environments with increasing
1579 autonomy — not as replacements for human judgment, but as participants in a
1580 collaborative intelligence that exceeds what either humans or machines achieve alone.
- 1581 • Without an architectural foundation that preserves manufacturing intent, context, and
1582 evidence as navigable, queryable structures, every deployment of an AI agent in
1583 manufacturing requires bespoke engineering. Data products must be constructed manually
1584 for each use case. Integration interfaces must be purpose-built to expose the specific data
1585 each agent needs. Explicit instructions must encode what matters, what relates to what, and
1586 why — effectively recreating by hand, for each agent, the contextual knowledge that a well-
1587 constructed IDDC would provide as architectural infrastructure. This is the same lifecycle
1588 discontinuity described in Section 4, now manifesting at the AI layer: the fragmentation of
1589 meaning that impedes technology transfer and batch disposition equally impedes the
1590 scaling of intelligent systems. The result is what industry practitioners increasingly
1591 recognize as pilot purgatory — so much effort devoted to constructing the prerequisites for

1592 each AI application that organizations exhaust their capacity for experimentation before
1593 reaching operational value.

1594 • With a functioning IDDC, the architectural situation inverts. The four layers — Semantic,
1595 Event, Context, and Evidence — collectively function as a navigable knowledge fabric that AI
1596 agents can traverse. An agent operating within this fabric can discover relationships
1597 between process parameters and quality attributes by querying the ontology. It can
1598 understand the temporal structure of manufacturing execution through the event layer. It
1599 can access the contextual bindings that explain why a measurement matters for a specific
1600 batch, material, or patient. It can evaluate the evidentiary record that supports or challenges
1601 a disposition decision. Critically, the ontology itself becomes an active enabler — not merely
1602 a reference that humans consult, but a machine-readable map that agents use to navigate
1603 systems and data, understand what they are observing, and determine appropriate actions
1604 within governed boundaries. The IDDC transforms agent deployment from a bespoke
1605 engineering exercise into an architectural capability: each new agent benefits from the same
1606 governed semantic foundation, the same contextual infrastructure, and the same
1607 evidentiary structures — compounding value rather than fragmenting it.

1608 • This vision is grounded in Malone's (2018) framework of collective intelligence and
1609 superminds — systems in which humans and machines collaborate to achieve outcomes
1610 that neither can achieve independently. In manufacturing, this collaboration is not
1611 hypothetical; it is already practiced in embryonic form. The AMP case study (Appendix A)
1612 illustrates the pattern concretely: human operators and a digital platform collaborate to
1613 disposition alarms, with the platform providing unified presentation and contextual
1614 evidence while humans exercise judgment on significance and response. With architectural
1615 maturity, this collaboration deepens. AI models could begin to pre-disposition certain
1616 alarms within defined boundaries — not replacing human judgment, but filtering noise,
1617 surfacing patterns, and presenting evidence in forms that accelerate human decision-
1618 making. This is the first step on the path from decision support to agentic operation,
1619 grounded in something that has already been built and is generating operational evidence.

1620 • The IDDC can be understood as a fabric from which different threads can be pulled —
1621 threads connecting systems, people, processes, and machines — and woven together to
1622 identify and surface opportunities or risks within operations and data. Organizations that
1623 invest in this fabric build architectural readiness: the capacity to adopt proven AI
1624 approaches rapidly as they emerge, because the data foundations, semantic structures, and
1625 evidentiary infrastructure are already in place. Without this readiness, the gap between
1626 observing what AI can achieve elsewhere and executing it internally becomes
1627 insurmountable. The fast follower strategy — deliberately adopting proven innovations
1628 rather than pioneering them — degrades from a strategic choice into involuntary
1629 stagnation, because each new AI initiative must first reconstruct the architectural
1630 prerequisites that a well-designed IDDC would have provided from the outset.

1631 • Early industry examples offer partial validation of this trajectory. Organizations that have
1632 publicly described successful AI scaling in pharmaceutical manufacturing consistently
1633 emphasize that architectural foundations preceded analytical deployment — investment in
1634 unified data access, semantic consistency, and governed context created the conditions
1635 under which AI models could generalize beyond individual sites or use cases. These
1636 examples demonstrate a pattern consistent with the IDDC argument: AI value compounds
1637 when it operates on architecturally coherent data, and fragments when each application
1638 must construct its own contextual foundation.

- 1639
- 1640
- 1641
- 1642
- 1643
- 1644
- 1645
- 1646
- 1647
- 1648
- 1649
- 1650
- It should be stated clearly that agentic AI in regulated manufacturing remains a future direction, not a present reality. No published example demonstrates autonomous AI agents operating within GMP manufacturing environments with the degree of contextual understanding and governed authority described here. The contribution of this subsection is architectural logic, not empirical validation: if the IDDC provides what the preceding sections argue it provides — preserved intent, coherent events, bound context, and structured evidence — then the architectural prerequisites for agentic capability are satisfied by design. The BioPhorum framework validates that these are the prerequisites industry consensus identifies. What remains is the engineering, governance, and organizational maturation required to realize this potential — a trajectory that current investments in platforms like AMP, ontology infrastructure, and data architecture are actively advancing.

Key Takeaway

AI enablement in life sciences manufacturing is not achieved through technology adoption alone. It is achieved when the architecture preserves meaning, event coherence, contextual binding, and quality evidence across the lifecycle. The IDDC provides the architectural foundation that makes AI credible and scalable, transforming AI from isolated experimentation into a governed, lifecycle-capable decision-support capability suitable for regulated environments.

1651

-

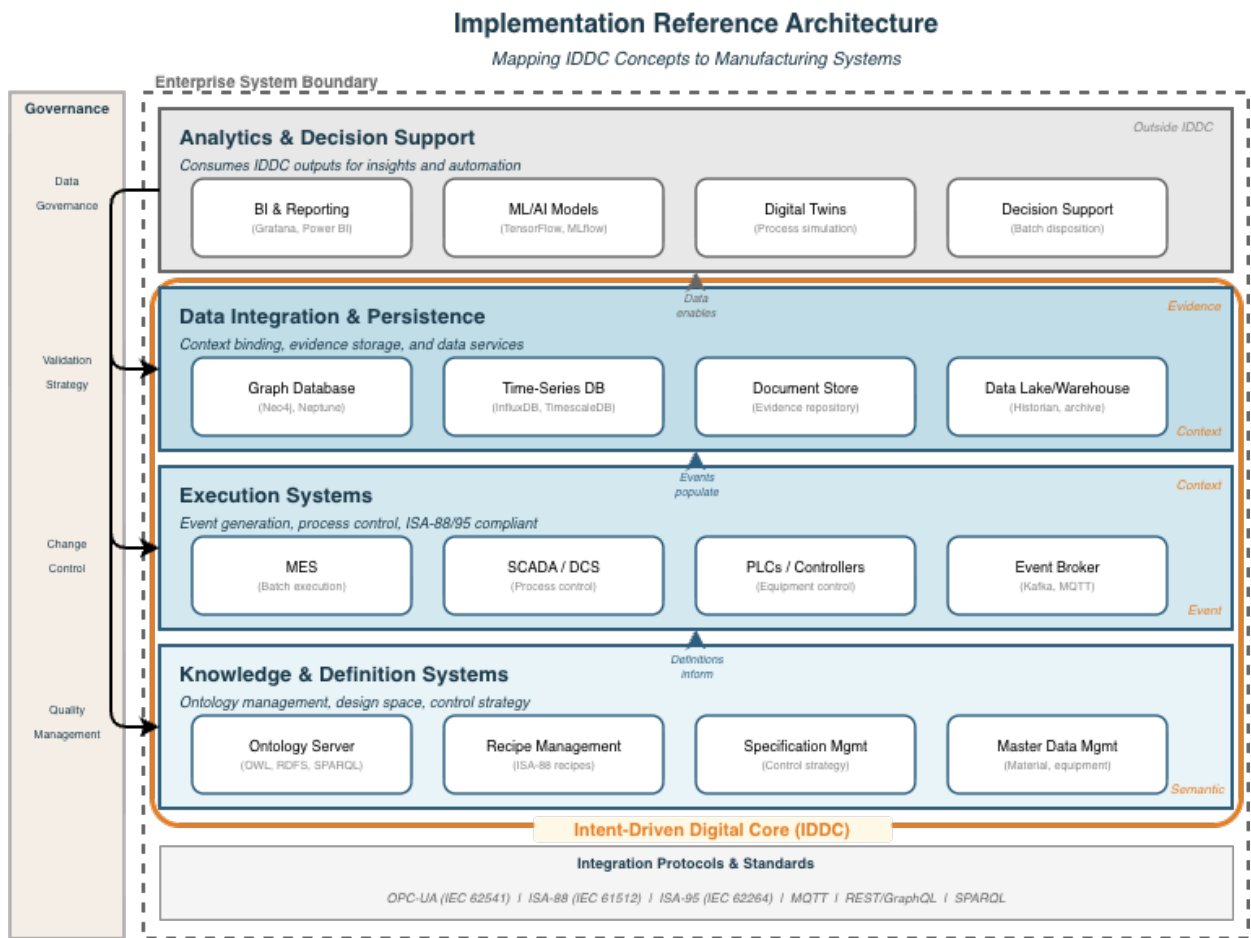

1652 11. REFERENCE ARCHITECTURE FOR LIFECYCLE-ALIGNED DIGITAL 1653 EXECUTION

- 1654
- 1655
- 1656
- 1657
- 1658
- 1659
- 1660
- 1661
- The preceding sections have established that sustainable digital value in life sciences manufacturing depends on preserving manufacturing intent, execution context, and quality evidence across the full product lifecycle. This section synthesizes those concepts into a reference architectural model, following established reference architecture practice as described in enterprise architecture frameworks such as TOGAF (The Open Group, 2018) and Zachman’s (1987) foundational work on information systems architecture, that illustrates how lifecycle continuity can be achieved without prescribing specific technologies, platforms, or organizational structures.
 - The purpose of this reference architecture is not to define a target system landscape—an approach that would contradict the technology-agnostic principles of established EA frameworks (The Open Group, 2018)—but to articulate the architectural responsibilities required to support scalable execution, digital tech transfer, continuous batch disposition, credible AI enablement, and more.

1667 11.1. ARCHITECTURAL DESIGN PRINCIPLES

- 1668
- 1669
- 1670
- 1671
- 1672
- The reference architecture presented here is governed by several core design principles derived directly from the analysis in earlier sections:
 - Lifecycle first
 - Architectural constructs must span discovery, development, manufacturing, and transfer, rather than optimizing for a single phase.

- 1673 • Intent before execution
- 1674 • Manufacturing intent must be explicitly defined and governed independently of any
- 1675 execution environment.
- 1676 • Meaning over movement
- 1677 • Preserving semantic meaning and context is more critical than maximizing data flow or
- 1678 centralization.
- 1679 • Evidence by design
- 1680 • Quality-relevant evidence must be generated continuously as execution occurs, not
- 1681 reconstructed retrospectively.
- 1682 • Decoupled but coherent
- 1683 • Systems may evolve independently, but architectural meaning must remain stable.
- 1684 • These principles ensure that the architecture remains durable as products, sites, and
- 1685 technologies change. They reflect the separation of concerns that is central to enterprise
- 1686 architecture practice (Zachman, 1987; The Open Group, 2018) while grounding each
- 1687 principle in the specific regulatory and operational requirements of life sciences
- 1688 manufacturing. Figure 7 provides a visual representation of this reference architecture,
- 1689 illustrating how the architectural domains relate to one another and to the IDDC.
- 1690 •

1691
1691
1692 • Figure 7. Implementation Reference Architecture mapping enterprise systems to IDDC concepts. The three lower layers implement IDDC capabilities; Analytics consumes IDDC outputs. See Figure 2 for conceptual IDDC architecture.

- 1693 • As shown in Figure 7, the reference architecture positions the IDDC as the central substrate
1694 connecting the Manufacturing Intent Domain, Execution Domain, Context and Evidence
1695 Domain, Integration Domain, and Governance Domain. The layered model demonstrates
1696 how intent flows from definition through execution to evidence, with each domain
1697 maintaining clear responsibilities while contributing to lifecycle continuity. Importantly, the
1698 figure illustrates that the architecture is technology-agnostic: specific tools and platforms
1699 can be selected based on organizational context, provided they fulfill the architectural
1700 responsibilities defined for each domain. This approach enables incremental adoption and
1701 respects existing system investments while establishing the structural foundation for
1702 scalable lifecycle capabilities.

1703 11.2. CORE ARCHITECTURAL DOMAINS

- 1704 • At a high level, the reference architecture can be understood as a set of interrelated
1705 domains, each with a distinct responsibility.

1706 11.2.1. MANUFACTURING INTENT DOMAIN

- 1707 • This domain is responsible for defining and governing manufacturing intent across lifecycle
1708 phases, operationalizing the concepts of design space and control strategy from ICH Q8(R2)
1709 (ICH, 2009) and the lifecycle knowledge management requirements of ICH Q10 (ICH, 2008).
1710 It includes explicit representations of:

- 1711 • process objectives and constraints,
 - 1712 • critical quality and process attributes,
 - 1713 • control strategies and acceptance criteria,
 - 1714 • relationships between materials, equipment roles, and process stages.
- 1715 • Importantly, intent is versioned and traceable, enabling controlled evolution as knowledge
1716 matures from development through commercialization. To the extent possible, these
1717 representations should be structured data. Where documents are needed for consumption
1718 by humans, they should be generated deterministically for consistency.

1719 11.2.2. EXECUTION DOMAIN

- 1720 • The execution domain encompasses control systems, manufacturing execution systems,
1721 laboratory systems, and other platforms responsible for carrying out manufacturing
1722 activities. These systems are typically organized according to ISA-88 (IEC 61512)
1723 procedural control hierarchies and ISA-95 (IEC 62264) activity models, which provide the
1724 structural framework within which execution events are generated and interpreted.
- 1725 • Within the reference architecture, execution systems are not required to be uniform or
1726 centrally governed. Their architectural responsibility is to:
- 1727 • expose meaningful execution events,
 - 1728 • associate those events with the applicable intent in effect at the time,
 - 1729 • preserve temporal coherence and state transitions.
- 1730 • This allows execution reality to be captured faithfully without constraining local
1731 implementation choices.

1732 11.2.3. CONTEXT AND EVIDENCE DOMAIN

- 1733 • The context and evidence domain binds execution events to the semantic and operational
1734 context necessary for interpretation. This includes:

- 1735 • process and phase context,
- 1736 • material and batch lineage,
- 1737 • equipment configuration and role context,
- 1738 • quality expectations and applicable limits.
- 1739 • Evidence generated within this domain is structured to support downstream quality review,
- 1740 regulatory inspection, and analytical consumption without additional reconciliation.

1741 11.2.4. INTEGRATION AND INTEROPERABILITY DOMAIN

- 1742 • Rather than focusing on point-to-point integrations, this domain ensures that systems
- 1743 interoperate against shared meaning. Ontologies, canonical event structures, and governed
- 1744 interfaces enable systems to exchange information without semantic loss. This approach
- 1745 reflects Evans's (2003) domain-driven design principle of a "ubiquitous language"—a
- 1746 shared vocabulary that bridges technical and domain experts—and applies Hohpe and
- 1747 Woolf's (2003) enterprise integration patterns to ensure that messaging and data exchange
- 1748 preserve semantic fidelity across system boundaries.
- 1749 • This domain is where lifecycle portability is achieved, supporting both technology transfer
- 1750 and AI generalization.

1751 11.2.5. GOVERNANCE AND STEWARDSHIP DOMAIN

- 1752 • The reference architecture assumes that architectural continuity is actively stewarded.
- 1753 Governance mechanisms define:
 - 1754 • ownership of intent and semantic definitions,
 - 1755 • accountability for data products and evidence quality,
 - 1756 • change management for evolving processes and models,
 - 1757 • lifecycle oversight for analytics and AI capabilities.
- 1758 • Governance is positioned as an enabling function, ensuring consistency without
- 1759 constraining execution.

1760 11.3. THE ROLE OF THE INTENT-DRIVEN DIGITAL CORE

- 1761 • The IDDC sits at the center of this reference architecture as the unifying construct that binds
- 1762 intent, execution, context, and evidence across domains.
- 1763 • Rather than acting as a monolithic system, the IDDC represents a persistent architectural
- 1764 foundation that:
 - 1765 • maintains semantic continuity as processes evolve,
 - 1766 • preserves event coherence across systems and sites,
 - 1767 • accumulates quality-relevant evidence progressively,
 - 1768 • enables downstream capabilities to consume trustworthy representations of manufacturing
 - 1769 reality.
- 1770 • In this model, analytics, AI, digital twins, batch disposition, and tech transfer are consumers
- 1771 of the core, not extensions of it. This distinction ensures that value compounds as
- 1772 capabilities are added, rather than fragmenting with each new initiative. In enterprise
- 1773 architecture terms, the IDDC functions as the canonical data model (Hohpe & Woolf, 2003)
- 1774 that decouples consumers from the operational systems that generate data, enabling new
- 1775 capabilities to be added without redesigning the foundational infrastructure.

1776 11.4. ARCHITECTURAL OUTCOMES ACROSS THE LIFECYCLE

- 1777 • When implemented coherently, the reference architecture supports several critical
1778 outcomes:
- 1779 • Scalable technology transfer, enabled by portable intent and comparable evidence
- 1780 • Continuous batch disposition, supported by progressive evidence accumulation
- 1781 • Credible analytics and AI, grounded in semantically stable, contextualized data
- 1782 • Reduced manual reconciliation, shifting effort toward informed judgment
- 1783 • Improved regulatory confidence, driven by traceability and evidence integrity
- 1784 • These outcomes emerge from architectural alignment, not from the optimization of
1785 individual systems.

1786 11.5. FROM REFERENCE MODEL TO ORGANIZATIONAL ADOPTION

- 1787 • The reference architecture is intentionally abstract. Organizations will instantiate it
1788 differently based on their operating models, technology landscapes, and regulatory
1789 strategies. The ISPE Pharma 4.0 Digital Maturity Model (ISPE, 2023) provides a useful
1790 assessment framework for this instantiation, enabling organizations to evaluate their
1791 current capabilities against the architectural responsibilities defined here. However,
1792 successful adoption consistently requires:
- 1793 • explicit recognition of intent and evidence as lifecycle assets,
- 1794 • alignment of people and roles with architectural responsibilities,
- 1795 • governance models that prioritize continuity over local optimization,
- 1796 • phased implementation that strengthens foundations before advanced analytics and AI.
- 1797 • Importantly, organizations need not reach full maturity across all domains simultaneously.
1798 Value can be realized incrementally, provided architectural coherence is preserved.

Key Takeaway

A lifecycle-aligned digital architecture is defined by responsibilities, not tools. By centering intent, preserving context, and generating evidence by design, the reference architecture described here provides a durable foundation for scalable manufacturing, digital tech transfer, continuous quality oversight, and trustworthy AI across the life sciences manufacturing lifecycle.

- 1799 •

1800 12. GOVERNANCE AND OPERATING MODEL IMPLICATIONS

- 1801 • The architectural strategy described in this paper cannot be sustained through technology
1802 decisions alone. Preserving manufacturing intent, contextual integrity, and evidence across
1803 the lifecycle requires an operating model that aligns accountability, decision rights, and
1804 stewardship with the architecture itself. Governance, in this context, is not a compliance
1805 overlay or a project control mechanism; it is how architectural continuity is maintained as
1806 products, processes, and capabilities evolve. While established data governance
1807 frameworks such as DAMA-DMBOK (DAMA International, 2017) provide foundational
1808 principles for data management, the governance demands of an intent-driven architecture

1809 extend beyond data stewardship to encompass semantic governance, evidence lifecycle
1810 management, and cross-functional accountability for manufacturing intent.

1811 • This section examines the governance and operating model implications of an intent-driven
1812 digital architecture, with particular attention to how emerging AI capabilities fundamentally
1813 change what must be governed and how.

1814 12.1. LIFECYCLE OWNERSHIP OF MANUFACTURING INTENT

1815 • In traditional operating models, ownership of manufacturing intent is fragmented.
1816 Development teams define process understanding, manufacturing teams focus on
1817 execution, and quality organizations interpret evidence retrospectively. As products move
1818 across lifecycle phases, intent is re-expressed through documents, specifications, and
1819 system configurations, often without a single accountable owner. ICH Q10 (ICH, 2008)
1820 recognizes this fragmentation as a barrier to effective pharmaceutical quality systems,
1821 while ICH Q12 (ICH, 2019) attempts to address it through the concept of established
1822 conditions that create explicit lifecycle ownership of critical process parameters.

1823 • An intent-driven architecture requires a different model: manufacturing intent must be
1824 owned as a lifecycle asset. Governance mechanisms must ensure that intent is explicitly
1825 defined, versioned, and stewarded as it evolves from discovery through commercialization
1826 and technology transfer. This does not imply centralization of authority, but rather clarity of
1827 accountability for how intent is represented and preserved. Mintzberg's (1979) analysis of
1828 organizational design demonstrates that effective coordination can be achieved through
1829 standardization of outputs and skills rather than centralization of decision-making—a
1830 principle directly applicable to governing manufacturing intent across distributed
1831 organizations.

1832 • Lifecycle ownership of intent enables several critical outcomes:

- 1833 • controlled evolution of process definitions as knowledge matures,
- 1834 • consistent interpretation of expectations across sites and partners,
- 1835 • traceability between development assumptions and manufacturing execution,
- 1836 • and alignment between quality decisions and original process objectives.

1837 • Without explicit ownership, intent inevitably degrades into locally interpreted artifacts,
1838 undermining the architectural foundation.

1839 • Cross-Functional Accountability by Design

1840 • The IDDC collapses traditional boundaries between IT, OT, and Quality by design. Semantic
1841 consistency, event coherence, and evidence integrity cannot be maintained within
1842 functional silos. As a result, governance models that rely on functional handoffs or system-
1843 centric accountability become liabilities.

1844 • Effective governance in this model is cross-functional by default. Accountability is aligned to
1845 architectural responsibilities rather than organizational units. For example:

- 1846 • intent stewardship spans development, manufacturing, and quality,
- 1847 • data product ownership crosses operational and analytical domains,
- 1848 • evidence integrity involves both execution and quality functions.

1849 • This shift does not eliminate functional expertise. Instead, it requires governance structures
1850 that explicitly manage interdependencies and shared ownership. Decision rights must be

1851 clear not only within functions, but across them, particularly where architectural
1852 consistency is at stake.

1853 12.2. THE EVOLVING ROLE OF CENTERS OF EXCELLENCE

- 1854 • Centers of Excellence (COEs) are commonly established to accelerate digital initiatives,
1855 standardize tools, or concentrate expertise. In many organizations, however, COEs become
1856 control points that inadvertently slow delivery or fragment ownership by pulling
1857 responsibility away from operational teams. Galbraith (2014) identifies this as a common
1858 failure mode of lateral organizational mechanisms: structures intended to enable
1859 coordination instead become bottlenecks when they accumulate decision rights without
1860 corresponding accountability for outcomes.
- 1861 • Within an intent-driven architecture, the role of the COE must evolve. COEs are most
1862 effective when positioned as enabling functions, responsible for:
 - 1863 • defining and maintaining architectural standards,
 - 1864 • stewarding shared semantic models and patterns,
 - 1865 • enabling reuse of capabilities across the organization,
 - 1866 • supporting education and architectural literacy.
- 1867 • They should not function as solution factories or approval bottlenecks. The objective is
1868 architectural coherence, not centralized execution. When COEs are aligned to capability
1869 stewardship rather than project delivery, they reinforce continuity rather than constrain it.
1870 The ISPE Pharma 4.0 Operating Model (ISPE, 2019) advocates precisely this positioning,
1871 recommending that Centers of Excellence function as enabling capabilities that develop and
1872 maintain organizational standards while empowering operational teams to execute within
1873 governed boundaries.
- 1874 • From Project Delivery to Capability Stewardship
- 1875 • Many digital programs are governed as projects with defined start and end points. While
1876 effective for system implementation, this model is poorly suited to architectural constructs
1877 that must persist and evolve over time.
- 1878 • An intent-driven digital architecture demands a shift from project delivery to capability
1879 stewardship. Core architectural elements such as semantic definitions, event models,
1880 evidence structures, and AI models are not “completed” at project close. They require
1881 ongoing stewardship, change management, and fitness-for-purpose assessment. GAMP 5
1882 (ISPE, 2022) provides the GxP-specific framework for this lifecycle approach to
1883 computerized system governance, while Kotter (1996) emphasizes that sustainable change
1884 requires institutional anchoring—embedding new practices in organizational culture and
1885 operational processes rather than relying on project-level momentum.
- 1886 • Operating models must therefore:
 - 1887 • recognize architectural capabilities as long-lived assets,
 - 1888 • fund stewardship alongside delivery,
 - 1889 • and define success in terms of sustained value rather than milestone completion.
- 1890 • This shift is particularly important for AI-enabled capabilities, which are inherently
1891 dynamic and sensitive to drift in data, process, and context.

1892 **12.3. GOVERNANCE IMPLICATIONS OF AI ENABLEMENT**

- 1893 • AI fundamentally changes the governance landscape. Unlike traditional analytics, AI models
1894 learn from data, adapt over time, and can influence decisions at scale. As a result,
1895 governance must extend beyond data access and model validation to include lifecycle
1896 assurance of meaning, context, and risk. The convergence of the NIST AI RMF (NIST, 2023),
1897 ISO/IEC 42001 (ISO/IEC, 2023), and the EU AI Act (European Union, 2024) establishes an
1898 emerging governance framework that requires risk-proportionate oversight, continuous
1899 monitoring, and explicit accountability for AI system performance throughout deployment.
- 1900 • Key governance implications include:
 - 1901 • explicit definition and approval of AI contexts of use,
 - 1902 • accountability for training data provenance and semantic fitness,
 - 1903 • monitoring for concept drift and process change,
 - 1904 • and integration of AI outputs into quality and operational decision frameworks.
- 1905 • Critically, AI governance cannot be bolted on after models are built. It must be embedded in
1906 the operating model that governs the IDDC. When intent, events, context, and evidence are
1907 preserved architecturally, AI governance becomes tractable. When they are not, AI risk
1908 escalates rapidly and confidence erodes. ICH Q9(R1) (ICH, 2023) reinforces this point:
1909 quality risk management must be systematic, science-based, and proportionate to risk—
1910 principles that apply with particular force to AI-enabled capabilities where the scope and
1911 pace of decision-making exceed what traditional governance models were designed to
1912 oversee.

1913 **12.4. GOVERNANCE WITHOUT OVER-SPECIFICATION**

- 1914 • A central risk in governance design is over-specification. Excessive control structures can
1915 stifle innovation and slow adoption, particularly in fast-moving development environments.
1916 The governance model implied by this architecture is therefore principle-driven rather than
1917 prescriptive.
- 1918 • Effective governance focuses on:
 - 1919 • what must remain consistent (intent, meaning, evidence),
 - 1920 • where flexibility is acceptable (local execution, tooling),
 - 1921 • and how change is managed transparently.
- 1922 • This balance allows organizations to scale digital capabilities, including AI, without
1923 sacrificing architectural integrity or regulatory confidence.

Key Takeaway

Architecture only delivers sustained value when it is matched by an operating model that governs intent, meaning, and evidence across the lifecycle. In an era of AI-enabled manufacturing, governance must evolve from project control and system oversight to capability stewardship and lifecycle accountability. Organizations that align governance to architectural continuity position themselves to compound digital value rather than repeatedly re-solve the same problems.

1924 •

1925 **13. CONCLUSION: FROM DIGITAL PROJECTS TO DIGITAL CONTINUITY**

- 1926 • The life sciences industry has invested heavily in digital technologies across discovery,
1927 development, and manufacturing. Yet the uneven realization of value from these
1928 investments suggests that the core challenge is not ambition, tooling, or effort, but
1929 architecture. Digital initiatives that are conceived and delivered as isolated projects struggle
1930 to scale, integrate, and endure because they do not preserve manufacturing intent, context,
1931 and evidence as products and processes evolve.
- 1932 • This paper has argued that digital continuity, rather than digital sophistication, is the
1933 defining requirement for sustainable value. Continuity is achieved not through system
1934 consolidation or advanced analytics alone, but through an architectural strategy that
1935 explicitly governs how meaning is defined, how execution reality is captured, and how
1936 evidence is accumulated across the lifecycle.

1937 **13.1. WHY ARCHITECTURE MUST PRECEDE ANALYTICS AND AI**

- 1938 • Advanced analytics and artificial intelligence are increasingly central to the future of
1939 pharmaceutical development and manufacturing. However, when deployed atop
1940 fragmented data landscapes, they amplify inconsistency rather than insight. Models trained
1941 on reconstructed, weakly contextualized data inherit the ambiguity and bias of their inputs
1942 —the “hidden technical debt” that Sculley et al. (2015) identify as the systemic risk of
1943 deploying machine learning on poorly governed data foundations—undermining trust and
1944 limiting applicability beyond narrow use cases.
- 1945 • By contrast, an intent-driven digital architecture establishes the conditions under which
1946 analytics and AI can compound in value. When manufacturing intent is explicit, execution
1947 events are coherent, context is bound at the point of generation, and evidence is preserved
1948 by design, analytical and AI capabilities consume a stable representation of reality. In this
1949 sequence, architecture is not a prerequisite that delays innovation, but the enabler that
1950 allows innovation to scale responsibly.
- 1951 • The BioPhorum consortium’s data characteristics framework reinforces this sequence
1952 empirically. Its four groups of AI-ready data requirements — data observability, data
1953 quality, data availability, and machine understandability — each presuppose capabilities
1954 that the IDDC’s architectural layers provide: observability depends on coherent event
1955 capture (Event layer), quality depends on governed semantic definitions (Semantic layer),
1956 availability depends on contextualized data products (Context layer), and machine
1957 understandability depends on traceable, structured evidence (Evidence layer). Without this
1958 architectural foundation, organizations pursue AI readiness as a data remediation exercise
1959 rather than an architectural outcome.

1960 **13.2. CONTINUITY AS THE MECHANISM FOR COMPOUNDING VALUE**

- 1961 • One of the most persistent frustrations in digital transformation is the need to repeatedly
1962 re-solve the same problems at each site, for each product, or at every lifecycle transition.
1963 This repetition is not inevitable. It is a consequence of architectures that do not carry
1964 meaning forward.
- 1965 • Digital continuity changes this dynamic. When intent, context, and evidence persist across
1966 phases and sites, knowledge compounds. Technology transfer becomes repeatable rather
1967 than bespoke. Batch disposition shifts from episodic reconstruction to continuous
1968 evaluation. AI models generalize across processes and facilities rather than being retrained

1969 in isolation. The BioPhorum data characteristics framework (BioPhorum, 2026) validates
1970 this at the consortium level: AI-ready data requires semantic consistency, contextual
1971 binding, and traceable provenance—characteristics that compound naturally within an
1972 intent-driven architecture.

- 1973 • In this model, value accrues not from individual digital projects, but from the accumulation
1974 and reuse of architectural assets.
- 1975 • The alarm management platform described in Appendix A illustrates this compounding
1976 pattern concretely. What began as event capture — unifying fragmented alarm data into a
1977 single, coherent record — enabled contextualized alarm disposition by operators and
1978 quality reviewers, which in turn generates progressive evidence for batch release decisions.
1979 Each architectural layer creates the conditions for the next. With sufficient maturity, the
1980 same platform positions the organization to deploy AI models that pre-disposition certain
1981 alarms within defined boundaries — not as a standalone analytics initiative, but as a natural
1982 extension of the architectural investment already made.

1983 13.3. WHAT ORGANIZATIONS GAIN FROM INTENT-DRIVEN DESIGN

- 1984 • Organizations that adopt an intent-driven digital architecture gain more than operational
1985 efficiency. They gain:
 - 1986 • confidence in decision-making, grounded in traceable evidence,
 - 1987 • agility in scaling processes and transferring technology,
 - 1988 • credibility in deploying AI within regulated environments,
 - 1989 • and resilience as systems, products, and regulatory expectations evolve.
- 1990 • Equally important, they shift the focus of digital transformation away from technology
1991 selection and toward architectural stewardship. This reframing aligns people, processes,
1992 and systems around a shared understanding of manufacturing reality—what Malone (2018)
1993 characterizes as the foundation for collective intelligence in organizations where humans
1994 and machines collaborate to produce outcomes neither achieves independently.

1995 13.4. LIMITATIONS

- 1996 • **Scope Boundaries.** This paper addresses digital architecture strategy for Chemistry,
1997 Manufacturing, and Controls (CMC) operations in pharmaceutical and biopharmaceutical
1998 manufacturing. The framework does not address discovery research, clinical trial
1999 operations, or commercial distribution and supply chain. While the architectural principles
2000 articulated here — preserving intent, binding context at execution, accumulating evidence
2001 progressively — may apply to adjacent domains, the specific regulatory grounding (ICH Q-
2002 series, GAMP 5, FDA and EMA guidance), industry examples, and consortium validation are
2003 drawn exclusively from manufacturing contexts. Applicability beyond this scope should not
2004 be assumed without independent evaluation.
- 2005 • **Methodological Boundaries.** The Intent-Driven Digital Core is developed through design
2006 science methodology — constructing and evaluating an architectural artifact against
2007 requirements derived from industry practice, regulatory expectations, and consortium
2008 consensus. It has not been subjected to controlled empirical validation across multiple
2009 manufacturing sites or organizations. The empirical evidence presented — the alarm
2010 management platform (Appendix A), the ontology deployment architecture (Appendix B),
2011 and the technology transfer analysis (Section 9) — demonstrates architectural feasibility
2012 and internal coherence rather than statistical generalizability. Each evidence stream

2013 illustrates how IDDC principles operate in practice; none constitutes a formal comparative
2014 study.

2015 • **Generalizability.** The regulatory and standards landscape that shapes this framework —
2016 GMP requirements, ALCOA+ data integrity expectations, ICH quality guidelines — is specific
2017 to pharmaceutical and biopharmaceutical manufacturing. Other regulated industries
2018 (medical devices, food safety, aerospace) share analogous requirements for traceability,
2019 data integrity, and lifecycle governance, but operate under different regulatory regimes
2020 with different enforcement mechanisms. Whether the IDDC’s specific architectural patterns
2021 transfer to these contexts, or whether the framework requires substantive adaptation,
2022 remains an open question.

2023 • **Economic Analysis.** This paper does not include cost-benefit analysis, return-on-
2024 investment modeling, or economic justification for IDDC adoption. The argument is
2025 architectural: that lifecycle discontinuity is a structural problem requiring an architectural
2026 response. Organizations evaluating adoption will need to develop their own economic
2027 models, accounting for implementation scope, existing system landscape, organizational
2028 readiness, and the opportunity cost of continued fragmentation.

2029 13.5. FUTURE RESEARCH DIRECTIONS

2030 • **Empirical Validation.** The most immediate research need is multi-site empirical validation
2031 of IDDC architectural principles. A cross-company study — conducted within a consortium
2032 context such as BioPhorum, the Pistoia Alliance, or NIIMBL — could evaluate whether
2033 organizations that adopt intent-driven architectural patterns achieve measurable
2034 improvements in technology transfer efficiency, batch disposition cycle time, and AI
2035 deployment success rates compared to organizations relying on conventional integration
2036 approaches. Such a study would require standardized maturity assessment instruments and
2037 longitudinal observation across implementation phases.

2038 • **Architectural Maturity Metrics.** This paper argues qualitatively that architectural
2039 coherence compounds value over time. Developing quantitative metrics for IDDC maturity
2040 — analogous to capability maturity models but specific to manufacturing digital
2041 architecture — would enable organizations to benchmark progress and prioritize
2042 investment. Metrics should address each IDDC layer independently (semantic
2043 completeness, event coherence, context binding coverage, evidence accumulation rate) and
2044 their integration collectively, distinguishing between organizations that have implemented
2045 individual layers and those that have achieved cross-layer architectural coherence.

2046 • **Cross-Industry Applicability.** Testing IDDC principles in adjacent regulated industries —
2047 medical devices under FDA 21 CFR Part 820, food manufacturing under FSMA, aerospace
2048 under AS9100 — would determine whether the framework’s regulatory grounding is
2049 industry-specific or whether the core architectural argument generalizes. The hypothesis is
2050 that the need to preserve design intent across lifecycle phases is universal in regulated
2051 manufacturing; the specific mechanisms and governance structures may require domain
2052 adaptation.

2053 • **AI Governance in Architecturally Coherent Environments.** Section 10 and the emerging
2054 vision for agentic manufacturing intelligence raise governance questions that this paper
2055 identifies but does not fully resolve. Research is needed on governance frameworks
2056 designed specifically for AI operating within intent-driven architectures — where models
2057 have access to contextualized, semantically grounded data rather than isolated datasets.
2058 The governance challenge shifts from data quality assurance to intent preservation

2059 assurance: ensuring that AI-driven decisions remain traceable to the manufacturing intent
2060 they are meant to serve.

2061 13.6. A CALL FOR ARCHITECTURAL DISCIPLINE

- 2062 • The transition from digital projects to digital continuity requires discipline. It requires
2063 resisting the temptation to optimize locally at the expense of lifecycle coherence. It requires
2064 investing in foundational constructs that may be less visible than dashboards or models, but
2065 far more consequential over time.
- 2066 • The IDDC described in this paper is not a prescription for a specific platform or operating
2067 model. It is a way of thinking about architecture as the mechanism by which intent becomes
2068 execution, execution becomes evidence, and evidence becomes knowledge.
- 2069 • As life sciences manufacturing continues to evolve in complexity and scale, the
2070 organizations that succeed will be those that treat architecture not as a technical artifact,
2071 but as a strategic asset.
- 2072 •

- APPENDIX: GLOSSARY OF SUPPORTING TERMS

• Term	• Definition
• Batch Disposition	• The formal quality decision to release or reject a manufactured batch based on review of execution records, test results, deviations, and supporting evidence.
• Control Strategy	• A planned set of controls derived from process understanding that ensures process performance and product quality across the manufacturing lifecycle.
• Critical Quality Attribute (CQA)	• A physical, chemical, biological, or microbiological property that must be maintained within defined limits to ensure product quality.
• Critical Process Parameter (CPP)	• A process parameter whose variability has a direct and significant impact on a critical quality attribute and must be controlled.
• Electronic Batch Record (EBR)	• A digital representation of manufacturing execution and quality data used to support batch review and disposition.
• GxP	• A collection of good practice guidelines that ensure products are safe, effective, and compliant with regulatory requirements.
• ALCOA+	• A set of principles ensuring data integrity by requiring data to be attributable, legible, contemporaneous, original, accurate, complete, consistent, enduring, and available.
• Data Integrity	• The completeness, consistency, and accuracy of data throughout its lifecycle, including its creation, modification, maintenance, and archival.
• Data Provenance	• Documentation of the origin, lineage, and transformations applied to data throughout its lifecycle.
• Event-Driven Architecture	• A design pattern in which system behavior and data capture are structured around discrete events and state changes rather than static records.
• Interoperability	• The ability of systems to exchange information and interpret it consistently without loss of meaning.
• Ontology	• A formal, machine-readable representation of concepts, relationships, and definitions within a domain, used to enable semantic consistency.
• Semantic Interoperability	• The ability of systems to exchange data with shared understanding of meaning, not merely shared syntax.

• Term	• Definition
• Unified Namespace (UNS)	• A logical data architecture pattern that exposes operational data in a consistent, real-time structure, commonly used in manufacturing contexts.
• Technology Transfer	• The process of transferring manufacturing knowledge, processes, and controls from development to manufacturing or between manufacturing sites.
• Lifecycle Phase	• A distinct stage in the product lifecycle, such as discovery, development, manufacturing, or technology transfer.
• Operating Model	• The combination of structures, processes, roles, and governance mechanisms by which an organization delivers value.
• Center of Excellence (COE)	• A centralized group established to provide expertise, standards, and enablement for specific capabilities or disciplines.
• Change Management	• The structured approach to managing modifications to processes, systems, or controls to maintain compliance and performance.
• Advanced Analytics	• Analytical techniques beyond descriptive reporting, including statistical modeling, optimization, and predictive methods.
• Artificial Intelligence (AI)	• Computational techniques that enable systems to perform tasks requiring human-like reasoning, learning, or pattern recognition.
• Machine Learning (ML)	• A subset of artificial intelligence in which models learn patterns from data rather than being explicitly programmed.
• Model Validation	• The documented process of ensuring that a model performs as intended within its defined context of use.
• Context of Use (AI)	• The specific conditions, assumptions, and decision boundaries under which an AI model is intended to operate.
• Explainability	• The degree to which the internal logic and outputs of a model can be understood by humans.
• Governance	• The framework of decision rights, accountability, and oversight used to ensure consistency, compliance, and strategic alignment.
• Risk-Based Approach	• A method of prioritizing controls and oversight based on the potential impact to quality, safety, or compliance.
• Regulatory Compliance	• Adherence to applicable laws, regulations, and guidance governing product development and manufacturing.
• Inspection Readiness	• The state of preparedness to demonstrate compliance and data integrity during regulatory inspection.

- APPENDIX A: ALARM MANAGEMENT PLATFORM CASE STUDY
- 1. EVIDENCE GENERATION THROUGH ARCHITECTURAL DESIGN: A PRACTITIONER IMPLEMENTATION
 - **Context:** Cell therapy manufacturing organization, clinical-stage biopharmaceutical production
 - 1.1. PROBLEM STATE: THE CHALLENGE OF DISTRIBUTED ALARM MANAGEMENT
 - **The Scale of Distributed Alarm Data.** Cell therapy manufacturing environments generate alarms across diverse equipment types—bioreactors, incubators, refrigerators, freezers, centrifuges, and analytical instruments. In the absence of a centralized platform, alarm data accumulates across individual systems, each with its own interface, storage format, and retention approach. This distribution is not a failure of design but a natural consequence of equipment being procured and deployed to meet evolving operational needs. The challenge becomes apparent when organizations seek to review alarm history holistically: recovery requires accessing each piece of equipment individually, and in many cases historical data has been archived to file shares where retrieval is neither straightforward nor timely.
 - **The Temporal Gap in Alarm Review.** When alarm acknowledgment and quality review occur separately from alarm generation—sometimes by days or weeks—organizations face an inherent challenge in reconstructing context. Alarms logged in batch records by operators were typically reviewed only when a deviation triggered an investigation. This approach is rational given resource constraints: not every alarm warrants detailed review, and quality organizations must prioritize their attention. However, it creates temporal disconnect between when an alarm occurred, when it was documented, and when its significance was assessed. This pattern reflects a broader industry challenge rather than an organizational shortcoming. The episodic, post-hoc evidence assembly described in Section 6.3 is common across pharmaceutical manufacturing precisely because it evolved within regulatory frameworks that emphasized final product testing over continuous process verification.
 - **The Stakes in Cell Therapy Manufacturing.** The consequences of delayed alarm visibility are amplified in cell therapy contexts. In autologous therapies, where one batch represents one patient, an alarm that goes unnoticed during a critical process window may contribute to batch loss. Such losses extend beyond operational metrics—they represent patients who may need to repeat the substantial physical and emotional burden of providing starting material for their own therapy. This patient-centric framing underscores why architectural approaches to alarm management warrant investment, even when existing processes are functioning adequately by traditional measures.
 - **Opportunity for Architectural Improvement.** Quality Operations recognized an opportunity to move from reactive alarm review to proactive disposition. The personnel who would benefit most from a centralized platform had been seeking solutions but were constrained by technical complexity and competing priorities. The implementation described here emerged from this recognition—not as a correction of failure, but as an architectural evolution enabling capabilities that distributed systems could not practically provide.

2348 1.2. SOLUTION ARCHITECTURE

- 2349 • The Alarm Management Platform (AMP) was built on commercial SCADA infrastructure,
2350 utilizing edge nodes to capture and communicate data with equipment, processed by
2351 backend gateways, and presented via web interface. This was a purpose-built solution—not
2352 an off-the-shelf alarm management product—designed around three core capabilities: (1)
2353 Unified Presentation: present alarms from heterogeneous equipment sources in a single
2354 interface, eliminating the need to access each system individually; (2) Operator Interaction:
2355 enable operators to review, comment on, and acknowledge alarms with contextual
2356 annotation at or near the time of occurrence; and (3) Quality Review: allow quality
2357 reviewers to view and disposition alarms in real time alongside operations, shifting from
2358 retrospective reconstruction to contemporaneous assessment.

2359 1.3. IDDC ARCHITECTURAL MAPPING

- 2360 • The AMP implementation provides a concrete instantiation of three IDDC layers,
2361 demonstrating how the architectural framework translates into operational capability.
- 2362 • **Event Layer.** The Event Layer captures alarms and their relationships to equipment,
2363 process, and batch. Each alarm is stored as a discrete, time-stamped event with equipment
2364 identifier and role, process context (batch, phase, step), alarm type and severity
2365 classification, timestamp with sub-second precision, and initial state and triggering
2366 conditions. This event-centric representation enables accurate reconstruction of what
2367 occurred without retrospective inference—addressing the temporal coherence
2368 requirements described in Section 6.4.
- 2369 • **Context Layer.** The Context Layer binds human interpretation from operators and quality
2370 reviewers to each alarm event. This contextualization occurs contemporaneously with
2371 execution, documenting causation (why the alarm occurred), treatment (how it was
2372 addressed), resolution (whether and how it was resolved), and impact assessment (effect
2373 on batch quality and regulatory status). This binding of human judgment to execution
2374 events exemplifies what Malone (2018) characterizes as cyber-human collaboration
2375 essential to collective intelligence in socio-technical systems. The operator provides domain
2376 expertise and situational awareness; the system provides comprehensive visibility and
2377 structured capture. Together, they produce contextualized evidence that neither could
2378 generate alone.
- 2379 • **Evidence Layer.** The Evidence Layer produces structured output suitable for quality
2380 review and regulatory inspection: alarm lineage (complete history from generation through
2381 disposition), audit trail (personnel involvement with timestamps and actions), decision
2382 framework (rationale supporting batch status determination), and regulatory alignment
2383 (evidence structured to satisfy ALCOA+ principles). This evidence builds up during batch
2384 execution rather than being assembled after the fact—enabling the continuous disposition
2385 model described in Section 8.
- 2386 • **Semantic Layer Gap.** The current implementation does not fully realize the Semantic
2387 Layer. The intent of each alarm—why it exists, what CPP or CQA it protects—remains tacit
2388 knowledge rather than formally encoded in an ontological structure. A full IDDC
2389 implementation would formalize this alarm intent, enabling automated reasoning about
2390 alarm significance and supporting more sophisticated AI-assisted disposition (see Section
2391 10).

2392 1.4. CHANGE MANAGEMENT APPROACH

- 2393 • **Strategic Influencer Model.** Rather than approaching senior decision-makers directly with
2394 a technology proposal, the implementation team engaged a dedicated change manager who
2395 identified the right influencer within each organization—the person who understood
2396 operational realities and could frame the approach constructively for their peers and
2397 leadership. This reflects the principle that collective intelligence depends not only on
2398 individual capabilities but on the communication structures that connect them.
- 2399 • **Co-Development Partnership.** Quality Operations provided strong support once the
2400 platform’s potential became clear. Rather than receiving a finished tool, they became
2401 partners in development—contributing requirements, validating design decisions, and
2402 shaping the solution they would ultimately use. Specific contributions included definition of
2403 alarm disposition states, specification of critical information requirements, workflow design
2404 for operator-quality reviewer interaction, and acceptance criteria for evidence
2405 completeness. This partnership model improved solution fitness and created ownership
2406 that accelerated adoption.

2407 1.5. OUTCOMES AND OBSERVED IMPACT

- 2408 • Before implementation, preparing batch-related alarm data for disposition was a
2409 retrospective, multi-step reconstruction: identifying the equipment involved in a batch,
2410 establishing the time windows during which that equipment was in use, retrieving the
2411 alarms and events generated on that equipment during those windows, and delivering the
2412 assembled record to manufacturing and then quality reviewers only after manufacturing
2413 disposition had completed. This reconstruction typically took five to ten days, and extended
2414 further whenever an alarm required investigation or opened a deviation.
- 2415 • With the AMP, alarms are bound not merely to a batch but to the specific batch phase on the
2416 specific equipment, allowing alarms outside relevant operational phases to be excluded and
2417 critical-window alarms to be elevated concisely. Meaning is assigned to an alarm while it is
2418 still active and being triaged—or shortly after—by the operator or technician handling it,
2419 producing contemporaneous, structured input whose quality is higher because causation,
2420 response, resolution, and impact are recorded when they are clearest rather than
2421 reconstructed weeks later. Operators return to other work while disposition evolves, while
2422 quality representatives review the initial acknowledgement and actions in parallel, assess
2423 impact in real time, and draw on previously dispositioned similar or identical alarm
2424 situations to disposition alarms ahead of, or shortly after, batch completion.
- 2425 • Having all batch-related alarms dispositioned and review-ready reduced the disposition
2426 step by an average of two to three days. Measured against time-to-close-and-release, the
2427 overall saving was approximately three to five days per batch. Where an alarm still required
2428 a deviation, the investigation itself was shortened by one to two days, because operators no
2429 longer had to be re-engaged to reconstruct actions and impact for an alarm that had
2430 occurred days or weeks earlier. The platform did not remove the need to triage an active
2431 alarm and therefore did not materially change deviation detection; the savings were
2432 concentrated in post-batch manufacturing and quality review and in investigation.
2433 Incorporating this dispositioned alarm data and its disposition state into the electronic
2434 batch record for review by exception is expected to compress disposition time further.
- 2435 • Other effects were observed but not formally quantified. Improved alarm rationalization
2436 and classification, together with stronger notification and escalation, focused response and
2437 surfaced nuisance alarms for elimination, reducing the overall alarm burden; per-alarm

2438 review effort itself changed little, the benefit being the ability to begin review before batch
2439 completion. Reviewer hours and alarm-volume reductions were not measured, and these
2440 results reflect a single-site implementation rather than a controlled study—consistent with
2441 the evaluation scope described in the paper’s Limitations.

2442 1.6. AI ENABLEMENT PATHWAY

- 2443 • The platform’s digital, extensible architecture enables future use of AI models to pre-
2444 disposition certain alarms within defined boundaries, further reducing burden on quality
2445 personnel. This represents an entry point to the agentic AI capabilities discussed in Section
2446 10—demonstrating how IDDC infrastructure compounds in value over time as more
2447 sophisticated capabilities are layered upon the architectural foundation. Potential AI-
2448 assisted capabilities include pattern recognition (identifying alarm patterns associated with
2449 known root causes), risk stratification (prioritizing alarms requiring human attention based
2450 on historical impact), pre-disposition (automated disposition of routine, well-characterized
2451 alarm types within validated boundaries), and anomaly detection (flagging unusual alarm
2452 patterns that deviate from learned baselines). Each capability requires the semantic, event,
2453 context, and evidence structures that the AMP provides—validating the IDDC thesis that
2454 architectural readiness precedes AI enablement.

2455 1.7. LESSONS FOR IDDC IMPLEMENTATION

- 2456 • The AMP case study offers several lessons applicable to IDDC implementations more
2457 broadly. First, narrow architectural focus enables rapid delivery of demonstrable value
2458 while establishing patterns for future extension. Second, cyber-human design—explicitly
2459 positioning humans and machines in complementary roles—characterizes effective
2460 implementations. Third, treating evidence generation as a first-class architectural
2461 requirement distinguishes implementations that enable continuous disposition from those
2462 that merely digitize retrospective assembly. Finally, technical architecture alone is
2463 insufficient; change management, strategic influencer engagement, and co-development
2464 partnerships are essential to translating architectural capability into operational value.
- 2465 • *Note: Organization and platform vendor names have been anonymized. The author served as*
2466 *solution architect, sponsor, and implementer for this platform.*

2467 • APPENDIX B: ONTOLOGY AS ARCHITECTURAL INFRASTRUCTURE IN
2468 MANUFACTURING

2469 1. FROM SEMANTIC THEORY TO DEPLOYMENT REALITY: A PRACTITIONER
2470 ARCHITECTURE

2471 • **Context:** Cell and gene therapy manufacturing as bounded design scope; biopharmaceutical
2472 ontology ecosystem as architectural foundation

2473 • **Framing:** This appendix presents a design science artifact—a proposed ontology
2474 deployment architecture validated by alignment with international standards, consortium
2475 consensus (Pistoia Alliance, IOF, NIIMBL), and ISA-95/ISA-88 structural models. It
2476 addresses a question that existing ontology literature largely leaves unanswered: what does
2477 deploying an ontology in a manufacturing facility actually require of engineers, architects,
2478 and the systems they govern?

2479 1.1. THE DEPLOYMENT QUESTION

2480 1.1.1. WHAT ONTOLOGY LITERATURE DOES NOT ANSWER

2481 • The ontology literature for life sciences manufacturing has matured substantially.
2482 Foundational work on Basic Formal Ontology (Arp, Smith, & Spear, 2015), the Industrial
2483 Ontologies Foundry (IOF) Core specification, and domain-specific efforts such as the Pistoia
2484 Alliance CMC Process Ontology (CMC-O) and NIIMBL Biopharmaceutical Manufacturing
2485 Ontology (BPMO) have established a layered semantic framework spanning top-level
2486 philosophical distinctions through domain-specific manufacturing constructs.

2487 • What this literature does not systematically address is the architectural deployment
2488 question: where does the ontology reside in a manufacturing facility? How do operational
2489 systems—MES, SCADA, LIMS, historians—connect to and consume ontological structures?
2490 Who governs semantic definitions, and through what mechanisms do changes propagate
2491 across consuming systems? These are not theoretical concerns. They determine whether an
2492 ontology functions as an architectural enabler or remains an academic artifact disconnected
2493 from operational reality.

2494 1.1.2. THE DISTINCTION BETWEEN DEFINING MEANING AND DEPLOYING IT

2495 • An ontology defines entities, roles, relationships, and constraints that give data its meaning
2496 within a domain. Deploying that ontology in manufacturing requires translating these
2497 definitions into structures that operational systems can instantiate, integration layers can
2498 transport, data platforms can persist, and quality processes can consume. This translation is
2499 neither automatic nor trivial—it demands deliberate architectural design across multiple
2500 system boundaries.

2501 • The architectural argument of this appendix is therefore: **an ontology functions as a**
2502 **governed semantic backbone defining meaning, roles, and relationships—not as an**
2503 **operational system. Systems map to it rather than execute it.** Relationships are defined
2504 centrally, instantiated in MES, mapped at integration boundaries, materialized in data
2505 platforms, and consumed by analytics and quality processes.

2506 1.2. THE BIOPHARMACEUTICAL MANUFACTURING ONTOLOGY STACK

2507 1.2.1. LAYERED ARCHITECTURE

- 2508 • The biopharmaceutical manufacturing ontology ecosystem is converging toward a layered,
2509 interoperable architecture (see Figure 4 in the main text). This layering reflects a deliberate
2510 design principle: domain-agnostic foundations enable cross-industry reasoning, while
2511 progressively specialized layers address pharmaceutical, manufacturing, and modality-
2512 specific requirements.
- 2513 • **Foundational Layer (Domain-Agnostic):** Basic Formal Ontology (BFO) serves as the ISO-
2514 recognized top-level ontology (ISO/IEC 21838-2:2020), providing distinctions between
2515 continuants and occurrents, roles, qualities, and processes that are invariant across
2516 domains. BFO's formal rigor ensures that downstream ontologies inherit consistent logical
2517 structure, enabling reasoning that transcends any single manufacturing context.
- 2518 • **Mid-Level Layer (Cross-Industry Manufacturing):** The Industrial Ontologies Foundry
2519 (IOF) Core extends BFO into manufacturing, defining reusable patterns for planned
2520 processes, material roles, design specifications, events, and assets. IOF Core provides the
2521 semantic bridge between domain-agnostic philosophy and domain-specific manufacturing
2522 reality—establishing, for example, how a “planned process” relates to its realization, how
2523 materials participate in processes through defined roles, and how information content
2524 entities relate to the physical entities they describe.
- 2525 • **Domain Layer (Pharmaceutical and Regulatory):** Multiple concurrent efforts address
2526 pharmaceutical-specific semantics:
- 2527 • **CMC-O:** Pistoia Alliance CMC Ontology (CMC-O): Focused on ISA-88 and ISA-95 aligned
2528 process, recipe, and parameter semantics. CMC-O defines the Process Stage – Operation –
2529 Action hierarchy that structures how manufacturing processes are described, compared,
2530 and transferred.
- 2531 • **IDMP-O:** Operationalizes ISO IDMP standards into a computable ontology for medicinal
2532 product identity, composition, packaging, and regulatory context—providing the product-
2533 level semantics that link manufacturing execution to regulatory filings.
- 2534 • **NIIMBL BPMP:** Adds biologics-specific unit operation semantics at a finer-grained
2535 operational level than CMC-O, addressing the particular requirements of upstream and
2536 downstream bioprocessing.
- 2537 • **Allotrope Foundation Ontologies (AFO):** Standardize laboratory instrument, method, and
2538 result semantics, bridging manufacturing execution data with analytical and QC data.
- 2539 • **QUDT:** Provides canonical semantics for quantities, units, and dimensions—ensuring
2540 measurement consistency across laboratory, manufacturing, and data platform boundaries.
- 2541 • **Provenance Layer:** The W3C Provenance Ontology (PROV-O) offers a general model for
2542 representing data lineage, activities, agents, and derivations. When profiled for GMP use,
2543 PROV-O supports the audit trail, electronic signature, and traceability requirements that are
2544 foundational to batch disposition and regulatory inspection.

2545 1.2.2. MATURITY ASSESSMENT

- 2546 • The ontology ecosystem spans a range of maturity states, which has direct implications for
2547 deployment architecture:

- 2548 • **Established and production-ready:** BFO, OBO Foundry ontologies, IDMP-O (v1+),
2549 Allotrope Foundation Ontologies, QUDT.
- 2550 • **Released but maturing:** IOF Core (v1 beta, expanding adoption), Pistoia Pharma General
2551 Ontology (Phase 1 published).
- 2552 • **Actively in progress:** Pistoia CMC-O, NIIMBL BPMO.
- 2553 • This heterogeneous maturity means that a deployment architecture cannot assume all
2554 semantic layers are stable. The architecture must accommodate ontologies at different
2555 maturity stages—some as authoritative references, others as evolving consensus artifacts
2556 subject to versioned change management.

2557 1.2.3. IDENTIFIED GAPS

- 2558 • Four gaps are architecturally significant for manufacturing deployment:
- 2559 a) **Digital artifact semantics.** No widely adopted ontology module represents digital artifacts
2560 such as control logic, models, algorithms, and their lifecycle in GMP manufacturing. As AI
2561 and advanced analytics become execution dependencies, this gap becomes increasingly
2562 consequential.
- 2563 b) **Measurement modeling consistency.** Despite QUDT’s canonical representation of units,
2564 consistent patterns for representing measured qualities, specification limits, and
2565 measurement uncertainty across laboratory and plant data remain unevenly implemented.
- 2566 c) **Cell and gene therapy semantics.** Chain-of-identity, chain-of-custody, and patient linkage
2567 concepts are only partially addressed and lack a unified reference profile—a gap that
2568 becomes critical when ontology is deployed in CGT manufacturing contexts (see the CGT
2569 Manufacturing stress-test discussion later in this appendix).
- 2570 d) **Batch disposition domain model.** No open reference ontology module explicitly models
2571 batch disposition decisions, release-by-exception logic, and QA review artifacts in alignment
2572 with manufacturing, quality, and regulatory ontologies. Batch disposition remains an
2573 emergent capability that must be composed from multiple semantic layers rather than
2574 instantiated from a coherent disposition-specific model.

2575 1.3. DEPLOYMENT ARCHITECTURE: SIX LAYERS OF ONTOLOGICAL MAPPING

- 2576 • The central architectural contribution of this appendix is a six-layer model describing
2577 where and how ontological relationships are realized in a manufacturing facility. Each layer
2578 serves a distinct function; together, they translate governed semantic definitions into
2579 operational capability.

2580 1.3.1. GOVERNED ONTOLOGY LAYER

- 2581 • The governed ontology is not an operational system. It is the authoritative semantic
2582 reference to which all downstream systems map. In IOF Core / BFO terms, this layer defines
2583 role patterns, participation patterns, aboutness relationships, and plan and protocol
2584 specification semantics. Governance of this layer requires versioning, change control, and
2585 clear ownership—the same disciplines applied to other lifecycle-critical assets such as
2586 master batch records and regulatory filings.

2587 1.3.2. ONTOLOGY ACCESS AND DISTRIBUTION: HOW SYSTEMS STAY CURRENT

- 2588 • The deployment question that most directly affects practicing engineers is deceptively
2589 simple: where does the ontology actually live, and how do the systems that depend on
2590 semantic consistency—MES, SCADA, PLM, historians, LIMS, integration layers, data

2591 platforms, digital tech transfer platforms, and quality systems—access it? If this question is
2592 not answered architecturally, the ontology remains an intellectual asset rather than an
2593 operational one.

2594 • **Persistence and Hosting.** The governed ontology is maintained as a formal artifact—
2595 typically serialized in OWL (Web Ontology Language) or a functionally equivalent format—
2596 within a dedicated ontology management platform or repository. This is not a static file on a
2597 shared drive. It is a versioned, access-controlled asset served through an application layer
2598 that supports querying, validation, and change management. Candidate hosting approaches
2599 include dedicated ontology servers (e.g., platforms supporting SPARQL endpoints),
2600 semantic middleware embedded within integration infrastructure, or purpose-built
2601 ontology registries that expose semantic definitions through APIs. The specific technology
2602 choice is less architecturally significant than the requirement that the ontology be
2603 accessible programmatically, version-controlled, and governed with the same rigor as other
2604 lifecycle-critical reference data.

2605 • **Programmatic Access as the Architectural Principle.** The defining characteristic of an
2606 externalized ontology—what distinguishes it from embedded semantics—is that consuming
2607 systems access semantic definitions programmatically rather than through manual
2608 transcription. If engineers must read the ontology, interpret it, and manually configure each
2609 system to reflect its content, the architecture has not solved the harmonization problem; it
2610 has merely centralized the specification while leaving the same manual, error-prone
2611 translation in place. The architectural target is systems that consume the ontology directly
2612 through APIs, validate their configurations against it automatically, and synchronize when it
2613 changes—with human oversight governing the change process, not performing the
2614 transcription.

2615 • **Access Model.** The ontology repository exposes semantic definitions through queryable
2616 interfaces (SPARQL endpoints, REST APIs, or equivalent) that any consuming system can
2617 call. This access model applies uniformly across the architecture. Every system that creates,
2618 transforms, transports, or evaluates manufacturing data is a potential consumer, and all of
2619 them consume the same authoritative source through the same programmatic mechanisms:

2620 • **Configuration validation:** When PLM specifications are structured, MES master data is
2621 configured, SCADA alarm definitions are created, historian tag structures are defined, or
2622 UNS topic hierarchies are established, the system queries the ontology repository to
2623 validate that local definitions align with the current governed version. Misalignments are
2624 flagged automatically rather than discovered during downstream reconciliation or audit.
2625 This is particularly consequential at the PLM-to-MES boundary, where process
2626 specifications—limits, setpoints, material definitions, quality attributes—are currently
2627 transcribed manually from documents into execution system configurations. When both
2628 PLM and MES consume the same ontology programmatically, the specification and its
2629 executable instantiation reference the same governed semantic definitions, eliminating the
2630 transcription step and the validation burden it creates.

2631 • **Synchronized updates:** When the ontology evolves—whether through new process
2632 understanding, regulatory feedback, or consortium updates—the repository notifies
2633 consuming systems of the change. Each system assesses impact against its current
2634 configuration, identifies definitions that require update, and presents the required changes
2635 for validated deployment. The change propagation is automated; the approval and
2636 deployment follow established change control procedures.

- 2637
- 2638
- 2639
- 2640
- 2641
- 2642
- 2643
- 2644
- 2645
- 2646
- 2647
- 2648
- **Runtime resolution:** During execution, systems resolve ontology references through API calls or cached local replicas synchronized with the authoritative source. An alarm generated by SCADA can be contextualized against the current ontology to determine which CPP or CQA it protects. An MES batch record can reference the ontology to verify that material roles and process relationships are semantically current. A historian query can be enriched with ontological context to ensure that data retrieved from different time periods or different equipment is interpreted consistently. A digital tech transfer platform can compare process definitions across sites by resolving both against the same ontology, identifying semantic equivalences and gaps without manual cross-referencing. A PLM system can verify that a specification change is reflected consistently across every downstream system that consumes it. Runtime resolution extends to any system that benefits from semantic context, which in a manufacturing facility is effectively all of them.
 - **Audit and compliance queries:** Quality, regulatory, and governance functions query the ontology repository to verify that operational systems are aligned with the current semantic version, to trace how semantic definitions have evolved over time, and to assess the impact of proposed changes before they propagate. Because every consuming system declares which ontology version it implements, compliance verification becomes a queryable property of the architecture rather than a manual audit exercise.
 - **Version Synchronization.** Because multiple systems consume the same ontology, version management is architecturally critical. The ontology repository maintains explicit version history with change documentation. Consuming systems declare which semantic version they implement, creating a traceable map of semantic alignment across the facility. When a new version is published, the propagation follows a managed process: impact assessment is automated, configuration updates are generated programmatically, validation occurs against the new version, and deployment follows established change control.
 - **The Alternative: Embedded Semantics.** Without this access architecture, semantic definitions are embedded directly into each consuming system—authored in PLM documents, manually transcribed into MES master data, programmed into SCADA alarm descriptions, replicated across historian tag structures, duplicated in integration mappings, and reconstructed independently in tech transfer documentation for receiving sites. This approach works, and it is the current industry norm. Its cost is measured in harmonization effort and transcription risk: when a specification changes in PLM, every downstream system that consumed that specification must be identified, assessed, and updated through manual processes that are themselves sources of error. When a process transfers to a new site or CDMO, the semantic definitions embedded in the sending site’s systems must be extracted, interpreted, and re-embedded into the receiving site’s systems—precisely the lifecycle discontinuity described in Section 4. The ontology access architecture described here replaces that manual harmonization with programmatic synchronization—systems that consume a shared, versioned semantic reference and stay aligned through automated validation rather than human transcription.

2677 1.3.3. MES / EBR INSTANTIATION LAYER (ISA-95 LEVEL 3)

- 2678
- 2679
- 2680
- 2681
- 2682
- 2683
- At batch creation, the Manufacturing Execution System (MES) instantiates a network of ontological relationships, drawing on the governed ontology accessed through the mechanisms described in the Ontology Access and Distribution subsection of this appendix. ISA-95 structural objects provide the execution model; the ontology supplies meaning, roles, and traceability. Product Definitions map to Plan Specifications, Production Orders to Planned Processes, Material Lots to Material Entities with roles, Equipment to Material

2684 Artifacts, Personnel to Agents, and Production Schedules to Temporal Regions. The MES
2685 does not “run” the ontology—it instantiates relationships that the ontology defines, creating
2686 traceable links between manufacturing intent and execution reality.

2687 1.3.4. INTEGRATION / UNIFIED NAMESPACE LAYER (ISA-95 LEVEL 3-2 BOUNDARY)

2688 • At the integration boundary, ontological mappings contextualize execution data as it flows
2689 between systems: measurements are linked to the material lots they describe, material lots
2690 are linked to their derivation history, events are recognized within the context of specific
2691 processes and batches, and equipment and personnel participation is recorded with
2692 temporal precision. The integration layer—whether implemented as a Unified Namespace
2693 (UNS), event bus, or traditional middleware—must preserve these semantic relationships
2694 during transport.

2695 1.3.5. DATA PLATFORM / KNOWLEDGE GRAPH LAYER (ISA-95 LEVEL 4)

2696 • The data platform materializes ontological relationships as persistent, queryable structures.
2697 This layer enables capabilities that operational systems cannot practically provide: cross-
2698 batch comparison, cross-site equivalence assessment, trend analysis grounded in semantic
2699 consistency, and the knowledge graph structures that support advanced analytics and AI.
2700 Ontology identifiers serve as lineage anchors, cross-site equivalence mappings support
2701 technology transfer, and temporal versioning of semantic definitions preserves the ability to
2702 evaluate historical data against the intent in effect at the time of manufacture.

2703 1.3.6. CONSUMPTION LAYER: DISPOSITION, QMS, SUPPLY CHAIN, AND AI

2704 • The consumption layer is where the architectural investment in ontology produces its most
2705 visible returns. Batch disposition is not a standalone function applied to data after the fact.
2706 It is an emergent capability that depends on the consistent accumulation of semantically
2707 grounded evidence across all upstream layers. When the ontology architecture is intact,
2708 disposition becomes a role assertion on a material entity supported by traceable
2709 relationships spanning process execution, data generation, deviations, and specification
2710 conformance—the continuous disposition model described in Section 8.

2711 1.4. CGT MANUFACTURING AS ARCHITECTURAL STRESS TEST

2712 • Cell and gene therapy (CGT) manufacturing was selected as the bounded scope for this
2713 architectural analysis because it intensifies every dimension of the ontology deployment
2714 problem. Where small molecule manufacturing permits statistical abstraction, pooled lots,
2715 and aggregated quality assessment, CGT manufacturing demands: mandatory lot genealogy
2716 where no statistical sampling or lot aggregation is permitted; patient linkage where
2717 material identity is inseparable from the patient it serves; non-collapsible lineage where
2718 every derivation is individually traceable; and patient-specific disposition semantics where
2719 batch release applies to a therapy intended for a specific human being.

2720 • Each layer of the deployment architecture is intensified in CGT contexts. The governed
2721 ontology must include patient-linking role patterns and chain-of-identity semantics. MES
2722 production orders become patient-specific. Integration layer lot genealogy is non-
2723 collapsible. Contextualization services must maintain bidirectional genealogy across
2724 processing steps spanning days to months. The data platform must persist patient entity
2725 relationships across the full lifecycle including CDMO partnerships. And disposition applies
2726 to a specific patient’s therapy rather than a statistical population.

- 2727 • CGT manufacturing thus serves as a stress test that reveals architectural requirements
2728 which remain latent in less demanding modalities. The ontology deployment architecture
2729 that satisfies CGT requirements inherently satisfies small molecule requirements—but the
2730 reverse is not true.

2731 1.5. ISA-95 AS STRUCTURE, ONTOLOGY AS MEANING

- 2732 • A persistent concern in manufacturing digitalization is whether ontology-based
2733 architectures conflict with established automation standards. The architecture presented
2734 here is explicitly designed to demonstrate that ISA-95 and ontology serve complementary,
2735 non-competing functions. ISA-95 provides structural execution models: the object types,
2736 hierarchies, and information flows that automation systems implement. Ontology provides
2737 semantic meaning: the roles, relationships, and traceability that give ISA-95 objects their
2738 interpretive context. A Material Lot in ISA-95 terms is a structural container; in ontological
2739 terms, it is a Material Entity bearing specific roles with defined participation in processes
2740 and traceable derivation history.
- 2741 • This complementarity means ontology deployment does not require replacing ISA-95
2742 infrastructure. It requires extending existing structural objects with semantic annotations
2743 that enable cross-system interpretation, lifecycle traceability, and knowledge preservation.
2744 Manufacturing facilities operate within validated ISA-95 infrastructure that regulators
2745 understand and inspect against. An ontology deployment architecture that respects ISA-95
2746 structure while adding semantic capabilities can be presented to regulators as an
2747 enhancement to existing validated systems, not a replacement of them.

2748 1.6. CURRENT STATE AND HONEST ASSESSMENT

2749 1.6.1. INDUSTRY MATURITY

- 2750 • The biopharmaceutical industry’s relationship with manufacturing ontology is
2751 characterized by a widening gap between semantic infrastructure readiness and
2752 operational deployment. On the infrastructure side, substantial progress is evident: BFO is
2753 ISO-standardized, IOF Core is expanding adoption across manufacturing sectors, the Pistoia
2754 Alliance CMC-O and NIIMBL BPMP are actively developing domain-specific constructs, and
2755 digital infrastructure prerequisites—MQTT-capable edge architectures, modern SCADA
2756 platforms, cloud-connected MES systems—are increasingly common in new and renovated
2757 facilities.
- 2758 • On the deployment side, however, no published example of an end-to-end ontology
2759 deployment architecture in biopharmaceutical manufacturing has been identified by the
2760 author. Research and laboratory ontology implementations exist at several organizations,
2761 and individual ontology layers (particularly IDMP-O for regulatory submissions and AFO for
2762 analytical data) are in production use. But the full architectural stack described in this
2763 appendix—governed ontology through MES instantiation through integration-layer
2764 contextualization through knowledge graph materialization through quality consumption—
2765 remains unrealized at industry scale.
- 2766 • This gap is not primarily technical. The ontology components exist or are maturing; the
2767 standards alignment is achievable; the architectural patterns are sound. What remains is
2768 the organizational commitment, cross-functional coordination, and sustained investment
2769 required to compose these elements into a functioning deployment. The design science
2770 contribution of this appendix is the architecture itself—providing a validated blueprint that
2771 reduces the engineering uncertainty organizations face when making that investment.

2772 1.6.2. CROSS-INDUSTRY PERSPECTIVE

- 2773 • Other industries offer partial precedent. ISO 15926 in process industries (oil and gas)
2774 provides a long-running example of ontology-based information integration, though its
2775 scope and adoption challenges offer both encouragement and cautionary lessons. The
2776 Digital Twin Definition Language (DTDl) in discrete manufacturing demonstrates that
2777 semantic metadata can be bound to operational assets at scale. These cross-industry
2778 examples validate the general architectural pattern while highlighting that
2779 biopharmaceutical manufacturing’s unique regulatory, quality, and patient-safety
2780 requirements demand domain-specific instantiation.

2781 1.7. IMPLICATIONS FOR THE IDDC FRAMEWORK

- 2782 • The ontology deployment architecture described here directly supports the IDDC’s
2783 Semantic Layer—the foundational layer that strengthens the consistency and scalability of
2784 Event, Context, and Evidence capabilities. It is important to be precise about what ontology
2785 adds and what already functions without it. Manufacturing organizations routinely program
2786 semantic context into their systems—alarm descriptions reference process parameters,
2787 MES recipes encode relationships between materials and equipment, and integration layers
2788 map data between systems. These implementations work. The architectural concern is not
2789 that context is absent without ontology, but that it is implemented redundantly, maintained
2790 independently, and harmonized manually across systems and lifecycle phases:
- 2791 • **Events:** Events are captured with context programmed into each generating system—but
2792 that context is defined locally, creating risk of inconsistency when the same concept (e.g., a
2793 critical process parameter, an equipment role) is represented differently across SCADA,
2794 MES, and historian systems. Reconciling these representations requires manual
2795 intervention at each integration boundary.
- 2796 • **Context:** Context is added by humans and by system configuration—but without a shared
2797 semantic reference, maintaining consistency across systems demands ongoing
2798 harmonization effort that scales poorly as facilities grow in complexity. Two systems may
2799 both contextualize an alarm correctly in isolation while producing irreconcilable
2800 interpretations when their data converges downstream.
- 2801 • **Evidence:** Evidence is assembled through established quality processes—but the manual
2802 effort required to verify that evidence from multiple sources is semantically consistent
2803 represents a significant and recurring cost, particularly during batch disposition, technology
2804 transfer, and regulatory inspection.
- 2805 • Ontology does not create these capabilities where none exist. It externalizes and governs
2806 the semantic definitions that are currently embedded, duplicated, and independently
2807 maintained across systems—reducing harmonization burden, improving consistency at
2808 scale, and enabling the progressive evidence accumulation that supports continuous
2809 disposition (Section 8).
- 2810 • The AMP case study (Appendix A) illustrates this distinction concretely: the platform
2811 successfully realizes Event, Context, and Evidence layers through programmed context and
2812 human interaction. The Semantic Layer—formal encoding of alarm intent in ontological
2813 structures—remains unrealized, meaning the platform’s semantic definitions are
2814 maintained within the application rather than governed externally. The ontology
2815 deployment architecture described here would externalize those definitions, enabling

2816 consistent interpretation across AMP and all other systems that consume the same
2817 manufacturing concepts.

2818 • *Note: The author is a contributing member of the Pistoia Alliance CMC Process Ontology*
2819 *project. The architectural analysis presented here draws on publicly available consortium*
2820 *outputs, international standards, and the author's practitioner experience in cell therapy*
2821 *manufacturing digitalization. No proprietary organizational data is disclosed.*

2822 • APPENDIX C: RESEARCH METHODOLOGY

2823 2. METHODOLOGICAL FRAMEWORK

2824 • This research adopts a design science research methodology (Hevner et al., 2004; Peffers et
2825 al., 2007) to develop and evaluate an architectural framework for lifecycle continuity in
2826 pharmaceutical manufacturing. Design science is particularly appropriate for this work
2827 because it addresses a class of problems—digital transformation failures in regulated
2828 manufacturing—through the creation and evaluation of innovative artifacts (March &
2829 Smith, 1995). The primary artifact produced by this research is the Intent-Driven Digital
2830 Core: a reference architecture framework that prescribes how manufacturing intent,
2831 execution context, and quality evidence should be preserved across the product lifecycle.

2832 • Unlike purely empirical research that seeks to understand phenomena through observation,
2833 or purely theoretical research that develops conceptual models without implementation
2834 consideration, design science research bridges theory and practice by creating utility-
2835 oriented solutions grounded in rigorous analysis (van Aken, 2004; Gregor & Hevner, 2013).
2836 This methodological positioning acknowledges that the value of the proposed framework
2837 lies not only in its conceptual coherence but in its practical applicability to real-world
2838 manufacturing challenges.

2839 3. RESEARCH ACTIVITIES

2840 • The research followed the design science methodology proposed by Peffers et al. (2007),
2841 which structures design science research into six interconnected activities: problem
2842 identification and motivation, objectives of solution, design and development,
2843 demonstration, evaluation, and communication.

2844 3.1. PROBLEM IDENTIFICATION AND MOTIVATION

2845 • The research problem emerged from extensive engagement with pharmaceutical
2846 manufacturing organizations, grounded in over a decade of professional experience in
2847 pharmaceutical and biotechnology manufacturing systems and process automation. This
2848 practical foundation was complemented by active industry consortium participation,
2849 particularly the Pistoia Alliance CMC Process Ontology project (2023-2025) and review of
2850 BioPhorum Data Enablement Program materials. Further academic grounding is provided
2851 through the author's pursuit of the MIT Sloan Credential in Digital Business, including
2852 coursework in AI strategy, creative transformation, and algorithmic business thinking—
2853 perspectives that inform the architectural approach developed in this work. Analysis of
2854 digital transformation initiatives across the industry revealed a consistent pattern:
2855 substantial investment in digital technologies accompanied by limited realization of
2856 sustained, scalable value. Initial investigation focused on identifying whether these failures

2857 stemmed from technological inadequacy, organizational resistance, or more fundamental
2858 structural issues.

2859 • Through systematic analysis of technology transfer documentation, batch disposition
2860 processes, and digital maturity assessments, architectural discontinuity emerged as a
2861 primary causal factor. Manufacturing intent, execution context, and quality evidence were
2862 repeatedly reinterpreted, reconstructed, or lost entirely at lifecycle transitions. This
2863 observation motivated the central research question: *What architectural characteristics*
2864 *enable preservation of manufacturing meaning across the product lifecycle in regulated*
2865 *environments?*

2866 3.2. OBJECTIVES OF SOLUTION

- 2867 • Based on problem analysis, the research established four primary objectives for the
2868 architectural solution:
- 2869 2. **Preservation of Manufacturing Intent:** The architecture must support explicit, versioned,
2870 and traceable representation of what should be manufactured, under what constraints, and
2871 how success is determined—independent of any specific execution system or site.
- 2872 3. **Semantic Continuity Through Ontology:** The architecture must provide formal
2873 mechanisms for defining and governing the meaning of manufacturing concepts (processes,
2874 materials, equipment, quality attributes) such that interpretation remains consistent across
2875 systems, sites, and lifecycle phases.
- 2876 4. **Event-Driven Capture of Execution Reality:** The architecture must represent
2877 manufacturing execution as time-coherent events and state transitions, binding these
2878 events to relevant process, material, equipment, and quality context at the point of
2879 generation.
- 2880 5. **Progressive Evidence Accumulation:** The architecture must structure execution data as
2881 quality-relevant evidence with preserved lineage, provenance, and integrity, suitable for
2882 continuous disposition rather than retrospective reconstruction.

2883 3.3. DESIGN AND DEVELOPMENT

- 2884 • The Intent-Driven Digital Core framework was developed through iterative synthesis of
2885 regulatory requirements, international standards, and industry best practices. The design
2886 process proceeded through three stages:
- 2887 • **Stage 1: Regulatory and Standards Analysis**
- 2888 • Systematic review of regulatory guidance from FDA, ICH, EMA, and WHO established
2889 baseline requirements for data integrity, process validation, and lifecycle management.
2890 Analysis of international standards including ISA-88 (batch control), ISA-95 (enterprise-
2891 control integration), and IEC 62264 provided manufacturing domain abstractions. ICH Q8
2892 (pharmaceutical development), Q9 (quality risk management), Q10 (pharmaceutical quality
2893 system), and Q12 (lifecycle management) established quality system expectations.
- 2894 • **Stage 2: Ontological Foundation Development**
- 2895 • Through active participation in the Pistoia Alliance CMC Process Ontology project, the
2896 research engaged with pharmaceutical manufacturers, technology vendors, and standards
2897 bodies to develop shared semantic representations of manufacturing processes. This work
2898 established that semantic interoperability—not merely syntactic data exchange—was
2899 essential for lifecycle continuity. The ontological approach was further validated through
2900 examination of complementary initiatives including NIIMBL Biopharmaceutical

2901 Manufacturing Ontology and NIST Industrial Ontologies Foundry (IOF) work. Figure 4
2902 illustrates this ontology landscape, showing how foundational standards build toward
2903 domain-specific applications.

2904 • **Stage 3: Architectural Construct Synthesis**

- 2905 • The Intent-Driven Digital Core emerged as a unifying construct integrating four
2906 interdependent capabilities: semantic definition (ontology-based meaning), event
2907 representation (time-coherent execution reality), context binding
2908 (process/material/equipment/quality relationships), and evidence structuring (progressive
2909 quality-relevant accumulation). The architecture was deliberately positioned as technology-
2910 agnostic, defining responsibilities and relationships rather than prescribing specific
2911 implementations.

2912 3.4. DEMONSTRATION

- 2913 • The framework's utility was demonstrated through multiple mechanisms:
- 2914 • **Industry Consortium Validation:** The Pistoia Alliance CMC Process Ontology project
2915 (involving AstraZeneca, GSK, Johnson & Johnson, Eli Lilly, Merck, Amgen, and technology
2916 partners) provided real-world validation of the semantic layer concepts. The ontology's
2917 ability to represent processes across small molecules, biologics, and advanced therapy
2918 medicinal products (ATMPs) demonstrated practical applicability.
- 2919 • **Consensus Document Alignment:** The BioPhorum Digital Batch Disposition Manifesto (co-
2920 authored with industry participants including GSK, Vertex, Lonza, Abbvie, and technology
2921 vendors) validated the evidence accumulation and continuous disposition concepts. The
2922 manifesto's industry endorsement demonstrated consensus on architectural approaches to
2923 manufacturing intelligence.
- 2924 • **Reference Architecture Mapping:** The framework was mapped to established
2925 architectural patterns including event-driven architecture, domain-driven design, and data
2926 mesh principles, demonstrating conceptual soundness and alignment with broader
2927 architectural thinking.

2928 3.5. EVALUATION

- 2929 • Evaluation of the Intent-Driven Digital Core framework occurred through multiple lenses:
- 2930 • **Regulatory Alignment Assessment:** The architecture was systematically evaluated against
2931 regulatory expectations for data integrity (21 CFR Part 11, EU GMP Annex 11, ALCOA+
2932 principles), process validation (FDA 2011 guidance), and lifecycle management (ICH Q12).
2933 This assessment confirmed that the architectural approach not only supports compliance
2934 but enables more effective demonstration of control and understanding.
- 2935 • **Standards Conformance Analysis:** Alignment with ISA-88/95 object models, IEC 62264
2936 integration standards, and emerging AI governance frameworks (NIST AI RMF, ISO/IEC
2937 42001) was systematically verified. The architecture was positioned as an extension of—
2938 not replacement for—established standards.
- 2939 • **Industry Consensus Evaluation:** The framework's consistency with ISPE Pharma 4.0
2940 principles, BioPhorum data enablement recommendations, and World Economic Forum
2941 manufacturing digitalization research provided external validation of practical relevance.

- 2942 • **Architectural Stress Testing:** The framework was evaluated against challenging use cases
2943 including multi-site technology transfer, CDMO partnerships, continuous manufacturing
2944 scenarios, and AI model deployment in regulated contexts. These stress tests revealed
2945 where architectural clarity was most essential and where organizational capabilities
2946 required explicit design attention.

2947 3.6. COMMUNICATION

- 2948 • This paper represents the primary communication artifact, translating industry-grounded
2949 work into academic contribution. Additional communication occurred through:
- 2950 • Consortium workshop presentations (Pistoia Alliance CMC Ontology workshops, 2024-
2951 2025)
 - 2952 • Industry working group participation (BioPhorum Data Enablement Program)
 - 2953 • Technical documentation contributions (Batch Disposition Manifesto)
 - 2954 • The framing deliberately bridges industry practice and academic rigor, recognizing that
2955 architectural frameworks must be both theoretically sound and practically implementable.
2956 This integration reflects the author's direct experience: over a decade working across
2957 pharmaceutical and biotechnology organizations on manufacturing systems, process
2958 automation, and digital transformation initiatives has informed every aspect of this
2959 research—from problem identification through architectural design to evaluation of
2960 practical constraints.

2961 4. DATA SOURCES AND EVIDENCE BASE

- 2962 • The research draws upon multiple categories of sources:

2963 4.1. PRIMARY REGULATORY AND STANDARDS SOURCES

- 2964 • **Regulatory Guidance:** FDA (process validation, data integrity, AI/ML), ICH (Q8, Q9, Q10,
2965 Q12, Q5E), EMA (GMP Annex 11), WHO (technology transfer), PIC/S (data management)
- 2966 • **International Standards:** ISA-88 (IEC 61512), ISA-95 (IEC 62264), IEC 62541 (OPC UA),
2967 ASTM E2500 (pharmaceutical systems)
- 2968 • **Ontology Standards:** ISO/IEC 21838-2 (Basic Formal Ontology), IOF Core Ontology, QUDT
2969 (units and quantities)

2970 4.2. INDUSTRY CONSORTIUM MATERIALS

- 2971 • **Pistoia Alliance:** CMC Process Ontology project documentation, workshop presentations,
2972 phase reports, ontology release artifacts
- 2973 • **BioPhorum:** Data Enablement for AI reports, "What Is AI-Ready Data?" guidance, Digital
2974 Plant Maturity Model, Digital Batch Disposition Manifesto
- 2975 • **ISPE:** Pharma 4.0 Operating Model, GAMP 5 (2nd Edition), Pharma 4.0 Digital Maturity
2976 Model, AI in Pharmaceutical Manufacturing guidance
- 2977 • **NIIMBL:** Biopharmaceutical Manufacturing Ontology, big data program outputs
- 2978 • **NIST:** Industrial Ontologies Foundry materials, semantic interoperability research, AI Risk
2979 Management Framework

2980 4.3. SCHOLARLY LITERATURE

- 2981 • Design science research methodology (Hevner, March, Peffers, Gregor)
- 2982 • Enterprise architecture frameworks (Zachman, TOGAF)

- 2983 • Event-driven architecture patterns (Hohpe & Woolf, Fowler)
- 2984 • Ontology engineering (Gruber, Guarino, Arp et al.)
- 2985 • AI governance and lifecycle management (Mitchell, Gebru, Sculley)
- 2986 • Manufacturing systems and quality (ISA, IEC, pharmaceutical engineering literature)

2987 4.4. INDUSTRY RESEARCH, ANALYSIS, AND PRACTICAL MANUFACTURING EXPERIENCE

- 2988 • McKinsey & Company, Deloitte, PwC: Digital transformation studies, pharmaceutical operations research
- 2989 • World Economic Forum: Global Lighthouse Network reports, Industry 4.0 manufacturing
- 2990 • assessments
- 2991 • Gartner, Forrester: Technology landscape analysis, digital maturity frameworks
- 2992 • Practical manufacturing experience: Direct involvement in manufacturing systems
- 2993 • implementation, process automation, batch record design, technology transfer activities,
- 2994 • and digital transformation initiatives across pharmaceutical and biotechnology
- 2995 • organizations over more than a decade
- 2996

2997 5. SYNTHESIS APPROACH

- 2998 • The research employed a structured synthesis methodology integrating regulatory
- 2999 • requirements, industry standards, consortium insights, and scholarly literature into a
- 3000 • coherent architectural framework.
- 3001 • **Stage 1: Requirements Extraction**
- 3002 • Regulatory guidance and standards were systematically analyzed to extract explicit and
- 3003 • implicit architectural requirements. For example, FDA data integrity guidance (2018)
- 3004 • implies requirements for attribution, contemporaneous capture, and immutable recording
- 3005 • —which translate to architectural responsibilities for provenance tracking, event
- 3006 • timestamp binding, and append-only evidence structures.
- 3007 • **Stage 2: Gap and Discontinuity Analysis**
- 3008 • Industry consortium participation and manufacturing documentation review revealed
- 3009 • recurring patterns of semantic loss, contextual collapse, and evidence reconstruction. These
- 3010 • patterns were mapped to specific lifecycle transition points (development to
- 3011 • manufacturing, site to site, internal to CDMO) and categorized by architectural cause
- 3012 • (missing ontology, weak event coherence, inadequate context binding).
- 3013 • **Stage 3: Architectural Pattern Integration**
- 3014 • Established architectural patterns (event sourcing, domain-driven design, ontology-based
- 3015 • data access) were evaluated for applicability to pharmaceutical manufacturing constraints.
- 3016 • The Intent-Driven Digital Core emerged as a domain-specific instantiation of broader
- 3017 • architectural thinking, adapted for regulated lifecycle environments.
- 3018 • **Stage 4: Iterative Refinement**

- 3019 • The framework was iteratively refined through consortium engagement, particularly testing
3020 ontological approaches against multi-modality manufacturing requirements and validating
3021 evidence structures against batch disposition workflows.

3022 6. CONTRIBUTION TO KNOWLEDGE

- 3023 • This research makes three primary contributions:
- 3024 1. **Architectural Framework:** The Intent-Driven Digital Core provides a novel reference
3025 architecture specifically addressing lifecycle continuity challenges in regulated
3026 pharmaceutical manufacturing, bridging gaps between existing standards (ISA-88/95),
3027 regulatory expectations, and emerging digital capabilities.
 - 3028 2. **Ontology as Architectural Mechanism:** The research positions ontology not as an
3029 academic exercise but as a practical architectural construct essential for semantic
3030 interoperability across systems and lifecycle phases, validated through industry consortium
3031 development.
 - 3032 3. **Socio-Technical Integration:** By explicitly treating people, roles, and capabilities as
3033 architectural components rather than external users, the framework provides a more
3034 complete model of digital manufacturing systems in regulated environments.
